To provide a transport system for Wellington that meets the Paris Agreement's requirement to reduce carbon dioxide emissions by 80% will require reducing the emissions from transportation by the same amount. Could this be done? The average fuel consumption of the light vehicle fleet in 2000 was 9.75 litres/100 km (MoT, 2016, 4). An 80% reduction would mean cars with an average fuel consumption of under 2 litres of fuel per 100km. This seems unlikely to be achieved by 2050. Because of the slowness of the replacement of the New Zealand vehicle fleet, with the average age of vehicles now over 14 years (MoT, 2016, 4) it is not likely that new low-carbon technology, such as electric vehicles, will have sufficient time to replace existing vehicles before 2050. In addition, recent research shows that a change in New Zealand to an all-electric fleet of private cars would reduce emissions by only 60% (EECA, 2015, Table 15, 72) which is not enough. Other new technologies, such as driverless cars, will make transport easier so are unlikely to reduce travel distances and cannot be assumed to offer emissions reductions, since their focus is on control rather than fuel consumption. New technologies are also expensive currently compared to existing vehicles, making their likely uptake slow. The best that could be assumed is a halving of the average fuel efficiency of the existing fleet, to 4.9 litres per 100km by 2050. Petrol fuelled cars with this level of fuel consumption are already widely available, the eight year old Toyota Prius driven by one of the authors has a recorded lifetime average consumption of 4.6 litres per 100km.

Can we do it with behaviour?

Having halved vehicle emissions through the technology of reduced fuel consumption, the next strategy to achieve the target of 80% mitigation of emissions could be by halving the annual private vehicle travel. The present annual light vehicle travel in New Zealand is just over 11,000 km (MoT, 2016, 3) which could be reduced to say 6,000 km, although this would have to be achieved in line with an increase in regional population to nearly 650,000 by 2050 which will increase annual vehicle kilometres travelled (VKT), and in line with increased economic growth which could also increase VKT.

A Sustainable Perspective for Wellington (SuPerW) Approach to reduce travel distance

The different components of a future low-carbon transport system are discussed below under the heading of a Sustainable Perspective for Wellington (SuPerW) approach. The possible travel reduction assumed to be provided by each category is given after the discussion of that category.

SuPerW Built environment

A smart built environment has a crucial effect, albeit to varying degrees, on travel trends, with higher densities, a decent mix of uses and walkable neighbourhoods contributing to lower vehicle travel and fuel consumption. But at the same time public opinion is divided over preferences for green growth versus sprawl growth. Gross neighbourhood densities in the range of 1500 – 4000 persons per square km (ppsk) are found to act as the threshold for the most meaningful reductions in automobile travel (USDE, 2013). A recent study found that new patterns of built environment based on compact, walkable, easily accessible transit facilities could reduce GHG emissions from transportation sources up to 10% by 2050 which is equivalent to decrease in VKT by 15 % to 20% (USDE, 2013: 13). The land use impacts involved changes in neighbourhoods where ultimately vehicular travel is reduced by 20% to 40%. The *Moving Cooler* study (Urban Land Institute, 2009) found that VKT can be reduced by 2% to 13% based on built environment changes with gross densities of at least 1500 ppsk. Once suitable density exists, it generates destinations close to walk to, and reasonably competitive transit alternatives from a travel time and cost standpoint.

In the SuPerW strategy changes in the existing Wellington built environment are assumed to provide the conditions to promote reductions in VKT as set out below, by making easier the choice of modes of transport other than private cars.

Mode 1: Walking;
The cheapest, healthiest, environmentally friendly and space efficient way to travel is walking. Normally a person walking covers 1312 steps in 1km (Kyle's Converter, 2017). In NZ the amount of walking done per person per week varies by main urban centre or rural area (MoT, 2015). According to the USA Centres for Disease Control and Prevention "For the first time in history, the current generation of youth will live shorter lives than their parents" because of lack of exercise (Gotschi and Mills, 2008, 29). In recent decades we have consistently increased our calorie intake while decreasing our activity level. Especially in the last two decades the results of the obesity epidemic became apparent in sharply increased obesity rates (Flegal et al., 2002; Kuczmarski et al., 1994). A surprising 30% of private car trips in New Zealand are for less than 2 km (NZTA, 2016), a distance that could be walked, with additional economic, health and social benefits for society (LTSA, 2000). New Zealanders are undertaking fewer journeys per capita where walking is the sole mode of transport, there were 400,000 fewer walk-only trips in 1997/98 than in 1989/90. The number of walk-only trips rose slightly between 2005 and 2012 but the overall trend during the last decade shows a decreasing trend of 0.3% per year against population growth of 0.9% during the same period. The development of a dedicated walkway network for a community of 50,000 people would cost less than one km of motorway (NZTA, 2016). An increase in cycling could also be encouraged. Both these non-motorized modes of transport would be made considerably safer by the resulting reduction in car use. It is recommended for health that people walk 10,000 steps a day, a distance of 8 km (NHS Choices, 2014). If we all simply walked as recommended, this alone would be nearly 3000 km a year.

In the SuPerW strategy walking is assumed to be 1,500 km per year, half the 10,000 steps per day target.

Mode 2: Cycling;
The fastest (for shorter distances), good exercise and least expensive way to travel by vehicle is cycling. This mode of travel is good for local businesses as cyclists are often more likely to shop locally (City of Vancouver, 2011, 27). A fast growing development for encouraging cycling is electric bicycles. Electric bicycles offer multi-dimensional advantages of easy handling, cheaper and environmentally friendly transport for longer distance travel with easily overcome inclines and wind pressure and provision of load carrying capacity. These make this option an alternative to private cars for shorter trips as well as sensible choice for recreational activities (Wachotsch et al, 2014). The CDC recommendation for physical activity is 30 minutes of moderate exercise on most days (Gotschi and Mills, 2008, 29), equivalent to 8 Km of bicycling. By bringing this easy and simple change in transport behaviour it would be possible potentially to shift about 50% of car traffic load given that currently almost half of car travel trips are under 6 km long. (NZTA, 2011). The hilly terrain of the Wellington region might be a hurdle to shift this entire 50 % share to cycling, even with electric assistance. Annual car travel (as driver and passenger) in Wellington is just over 11,000 km per person (MoT, 2016, 3). Half of this distance is trips of less than 6 km that would be suitable for cycling, so it is assumed that around a third of these trips could be taken by cycling.

In the SuPerW strategy it is assumed that electric and pedal cycling may contribute around 2,000 km of cycle travel by 2050.

Mode 3: Public transport;

Wellington Region public transport has increased in the distance travelled per year from 345 million km in 1999/2000 to 430 million km in 2015/2016, an increase of 25% in 15 years. Over the same period, Wellington's bus and rail emissions have not increased (URS, 2014, Fig 5.59, 76). In spite of rising population, annual distance travelled per person on Wellington's public transport has also risen and is now around 1070km, compared with around 770 km in 2001 (calculated from data from Metlink, 2016 and Statistics New Zealand). If this rate of increase is increased through active promotion of public transport, it could result in a significant increase in public transport use in 30 years' time, meaning that at least 2,500 km of annual travel will be by public transport by 2050. This would comprise less than 25% of travel, in comparison, Vancouver intends 35% of travel to be by public transport by 2040 (City of Vancouver, 2011, 10). Subsidised public transport fares, free bus passes from employers, a well-connected efficient network, a new more comfortable bus fleet and other improvements will be needed to motivate the public to divert from private cars to public transport by 2050.

In the SuPerW strategy it is assumed that public transport will comprise 2,500 km of annual travel per person.

Mode changes: Summary

The suggested transport mode changes outlined above are in line with current trends and reflect realistic targets. The figures allocated to the different modes could change relative to one another but it appears that together non-car modes could amount to 6,000 km per person per year of travel, which is nearly 50% of total current annual travel in Wellington (12,231 km) (MoT, 2015b). This still leaves about 6,250 km of travel that is currently done in cars. The non-car modes are not necessarily zero-emission and strategies for moving public transport, in particular buses, from diesel to electric propulsion would be an essential part of a strategy for change. In Wellington, there is scope for introduction and implementation of policies similar to the TravelSmart programme that was used in Australia (DEH, 2005). This utilized a number of behaviour change techniques to reduce car use for household, commuting and school trips. It was found that a community based social marketing approach to persuade people onto other modes combined with measures to disincentivize car use (removing downtown parking) could change travel behaviour by reducing car use up to 60%. By shifting public to public transport up to 50% make possible CO_2 reductions ranging from 0.12-0.39 ton/capita/year.

The results

Table 1 presents the results of the application of the SuPerW Strategy to three possible scenarios for Wellington's passenger transport in 2050. In Table 1 the private car fleet is expected to rise from 277,000 in 2014 to 440,000 in 2050 as a result of population growth. Three scenarios are shown for assumptions about the amount of private car use in 2050, these are "Ideal", "Moderate" and "Business as Usual". The first assumes a modest reduction in car use, the second is as now and the third assumes greater distance travelled in 2050, but all are based on an increase in the size of the car fleet as well an increase in non-car modes as proposed in the SuPerW Strategy.

Table 1: 2014 passenger transport in Wellington and three scenarios for 2050

Wellington region	**2014**				**2050**					
	Fleet (1000)	Share in dist-ance	CO_2 emissions tonnes	Km pp/y	Fleet (1000)	Share in dist-ance	CO_2 emiss-ions tonnes	Km pp/y (per person per year)		
								Ideal	Mod-erate	Busi-ness as usual
Car	277	58%	703,000 65% of land transport*	7064	440	35%	142,562 65% of CO_2 target *	2,000	3,500	5,200
Car Passenger		31%		3736		22%		1,000	2,500	3,800
Pedestrian		2%		251		12%		1,500	1,500	1,500
Cyclist		1%		124		15%		2,000	2,000	2,000
Pub. Tran	0.75	8%	6,964 0.6% of land transport	1021	1.4	16%	2,200 1% of CO_2 target	2,500	2,500	2,500
CO_2 & fuel economy								108g/ km 4.3l/ 100k	54g/ km 2.3l/ 100k	36g/ km 1.6l/ 100k
Total			1,096,636	12,231			**220,820 CO_2 target**	9,000	12,000	15,000

* The remainder of the land transport emissions comprise 15% contribution from light commercial vehicles and 19.5% contribution from heavy commercial vehicles. These percentages are assumed to remain the same in the 2050 scenario.

Based on the required reduction in CO_2 emissions the car fleet can have total emissions of 142,562 tonnes per year. If annual travel distance reduces from over 12,000km per year to 9,000 (the "Ideal" scenario) the emissions for each car need to be 108kg CO_2/km. This equates to a fuel consumption of around 4.3 litres/100km. To put this into perspective, a UK based car review website states that there are already 524 models of cars on the market with CO2 emissions that fall into the range of 0 - 100g/km (CarPages, 2017). The emissions of light vehicles entering the New Zealand fleet have improved from about 220g CO_2/km in 2005 to 181g CO_2/km in 2015 (MoT, 2016, 56). Given this rate of reduction of 40 grams in ten years it is likely that the average emission of new vehicles could be 140g by 2030 and 100g by 2040, giving an overall fleet average of 100g by 2050.

It is important to note from Table 1 that both the "Moderate" and "Business as usual" scenarios would need much more radical changes in car technology to achieve the necessary emissions reductions. The "Ideal" scenario offers the lowest likely cost and is the simplest way to meet the Paris target.

Figure 1 shows the projected travel mode distance km per person per year in ideal scenario to be achieved in 2050.

Fig 1. Wellington Travel- travel mode distance in ideal scenario for 2050.

Conclusion

Overall the focus of this research is to accommodate the increased demand for travel due to the Wellington region's prosperity and population growth, to provide 80% reduction in transport generated greenhouse gas emissions and at the same time safe, affordable and easy access to home and work and amenities. This will require the implementation of policies, at local and national level, to change motivation towards using public transport, walking and cycling. Planning policies will need to encourage a built environment which actively promotes non-car travel. In addition there is a need to make all three non-car modes more attractive, reliable, and comfortable plus the promotion of more fuel-efficient cars. The aim is to bring about a behavioural change for a shift to public transport, walking and cycling and a reduction of 50% in private vehicle use. This could be a cost-effective way to meet the Paris target of an 80% reduction in emissions without the need for promoting expensive new technologies.

There is an answer for providing the kind of transport that Wellington needs to play its part in meeting the goals of the Paris Climate Agreement. It is not based on any radical change or futuristic technology, but can be achieved though using a combination of simple, available and affordable technology and simple changes in behaviour. We don't need to change our cars, we just need to change our minds.

Skycourt as a ventilated buffer zone in office buildings: assessing energy performance and thermal comfort

Saba Alnusairat[1], Phil Jones[1] and Shan Shan Hou[1]

[1] Welsh School of Architecture, Cardiff University, UK, alnusairatsf@cardiff.ac.uk

Abstract: Skycourts, recently, have been considered as beneficial spaces in commercial buildings, in particular offices. Skycourts are perceived as spaces that act as transitional and recreational nodes. Research considering the performance in response to conditions in these regions is steadily growing. However, there is a lack of conclusive results in the available literature about the actual energy performance of these spaces. The primary purpose of this paper is to examine the potential of the skycourt to perform as a buffer zone that suits to the ventilation strategy in office buildings in a temperate climate, thus could potentially reduce energy demands for heating and cooling, furthermore ensure thermal comfort in these spaces. Using a hypothetical reference office building in London, coupled Building Energy Simulation (BES) and Computational Fluid Dynamics (CFD) are carried out for two ventilation modes; mode one, the base model represents skycourt with isolated mechanical ventilation and mode two, alternative models that incorporate combined ventilation strategies with the adjacent offices' zones of the skycourt. These are simulated and evaluated regarding energy consumption and thermal comfort. Overall, the simulation results highlight that the incorporation of skycourt as buffer zone can potentially have a significant impact on the annual energy consumption.

Keywords: Skycourt, Buffer zone, Coupling simulation, Office buildings

Introduction

Skycourt is acknowledged nowadays as a beneficial space in buildings. This integrated area offers a modern alternative to the vernacular courtyard or atrium thus could support the social, environmental and economic functions in offices. For example, it can operate as common public space for social interaction, relaxation and leisure in areas, where there is usually lack of engagement between occupants. As well as, it might function as a transitional space to facilitate ease movement and clearness of wayfinding. Skycourt perhaps provides segmentation barriers between spaces. In addition, it can be integrated into the architectural design to benefit from the natural energy sources such as sun and wind to allow views and daylighting, and facilitate ventilation. Thus, it could provide significant outcomes of conserving energy and improving the health and wellbeing of occupants. Moreover, a skycourt could perform as buffer zone between the indoor and the outdoor consequently could mediate the climate conditions, provide thermal and acoustic protection to the interior, reduce heat loss and avoid unwanted solar gain. A growing body of literature has studied the influence of various integrated elements on the performance of buildings, such as skycourts (Ghazali et al, 2014; Pomeroy, 2014; Taib et al, 2010; Etheridge and Ford, 2008; Yeang, 1999). However, the weakness of current studies is the limitations in addressing the impact of such elements by its own on the total performance of the building.

This paper presents an independent study for the office's buildings in temperate regions, represented by London City underlines the function of skycourt as a buffer zone that located between the external façade and indoor controlled office zones, which are subject to mechanical ventilation. Heating and cooling processes consume approximately third of energy use in office buildings (Wood and Salib, 2013). Therefore, minimising energy demand by developing efficient strategies for ventilation, heating and cooling is crucial. This paper focuses on the potentials of skycourt to accomplish energy efficient solution stressing reduction of heating and cooling loads besides ensures thermal comfort in these spaces. It suggests several ventilation strategies relies on the fresh air required for the adjacent office's zones. The air movement causes convective heat transfer inside the skycourt under the buoyancy difference due to variation in temperature and height between the regions of the skycourt. This mechanism could induce thermal comfort significantly cooling without the need for consuming heating neither cooling loads for skycourt.

Methodology

Coupled Building Energy Simulation (BES) and Computational Fluid Dynamic (CFD)

Numerical simulations including Building Energy Simulation (BES) and Computational Fluid Dynamics (CFD) can provide a useful and quick prediction for the thermal conditions and energy performance of buildings. However, there are limitations in using these methods separately. Coupling BES and CFD simulation have generated considerable recent research interest. In this technique, two interrelated models are integrated to produce complementary detailed information by exchanging boundary conditions data. See Figure 1.

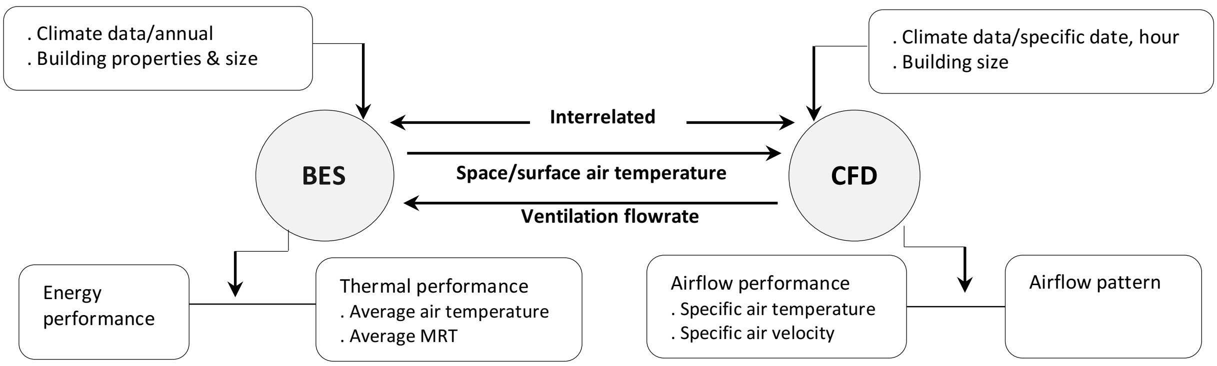

Figure 1. Diagram shows the BES and CFD coupling models

Coupling simulation is highly recommended in ventilation studies due to its accuracy and efficiency. This method could improve prediction of cooling and heating load at least 10% (Zhai et al, 2002). Furthermore, it might eliminate simulation time cost and requirements; it is found that full CFD requires about 12 hours with parallel workstation while coupling CFD requires less than one hour with 1 Gbytes computer to evaluate the same indoor environment (Wang and Wong, 2009). Integration between BES and CFD has been optimised with other numerical methods, theoretical analysis and experimental work. That is exemplified in the works undertaken by Barbason and Reiter (2014); Cropper et al (2010); Wang and Wong (2008); Zhai and Chen (2005); Zhai and Yan (2003); Bartak et al (2002). The validation showed that iteration between BES and CFD could produce correct and converged solutions and inform accurate and efficient prediction for thermal and airflow pattern in short time. Consequently, coupling could be considered as an advanced simulation tool to test the environment of different buildings.

The study aims to investigate the influence of several ventilation strategies in the skycourt space and compare the results regarding thermal comfort at the occupancy level and the energy consumption for heating and cooling. Therefore, coupling model is carried out to predict the performance. The building energy model, HTB2 and the airflow model, WinAir were integrated into the study. The ''Heat Transfer through Building'' (HTB2) was developed by the Welsh School of Architecture (WSA), Cardiff University. This numerical model can predict the indoor thermal performance and estimate the energy demands for buildings (Lewis and Alexander, 1990). HTB2 is recommended due to its high validity since it has been developed over thirty years. Furthermore, it has undergone a series of extensive testing including the IEA BESTEST (Neymark et al, 2011), IEA Task 12 (Lomas et al, 1994) and IEA Annex 1 (Oscar Faber and Partners, 1980) and. Also, it has been validated under ASHRAE standards and used to develop benchmarks for other standards (Alexander and Jenkins, 2015). Coupling HTB2 with WinAir as a CFD can accomplish graduating and accurate information of air temperature, air velocity and air concentration showing the airflow pattern in the skycourt. External coupling is adopted in this study; two models were built separately, a schematic model in the HTB2 and a grid model in the WinAir. The static strategy is carried out to bridge the two models; the thermal conditions for the CFD model are obtained from previously calculated values from the HTB2. These include the surfaces heat transfer, the inlet air supply, the outlet air exhaust and the internal heat gains involved inside the skycourt.

Coupling Simulation

The model is simplified to an eight-storey office building located in temperate climate represented by London. This building combines six-storey skycourt, the hollowed-out pattern. See Figure 2.

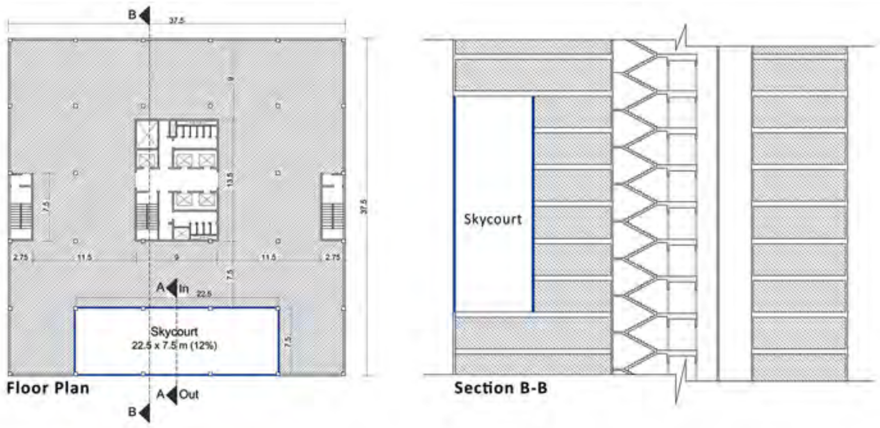

Figure 2. The spatial configurations of skycourt (the white shaded zone) considered in the study

Modelling framework

The simulation is carried out all over the year under different seasons: summer, winter and mid seasons using the HTB2. However, the CFD is measured considering the climate data for the peak summer hour, the coldest winter hour and the mid-temperature hour. These combine the following parameters: the hottest external temperature is 28.3°C on June 28th at 14.00, while the coldest external temperature is -5.0°C on December 7th at 9.00 am. The mid-temperature is 13.2°C on April 19 at 9.00 am. The adapted settings and conditions of the simulation process are defined in Table 1. Similar conditions are conducted for the six models except for the ventilation mode. However, the minimum ventilation rate to maintain an accepted air-quality is defined based on the number of occupants and taking into consideration the building envelope airtightness (infiltration). In the simulation, the heating set point is 18°C, and the cooling set point is 25°C. Single set point controls are used for cooling in the offices, while heating is controlled by air handling unit.

Table 1. Simulation settings for office spaces

Internal heat gain*		**Building Fabric**		**Ventilation setting**	
Workplace density	12 m^2 /person	Glazing U-value	1.5 (W/m^2.C)	Infiltration rate	3.5 $m^3/(m^2$.hr) at 50Pa
		g-value	0.4		
People	12 w/m^2	Window to wall ratio	70%	Air supply rate	10 L/s per person
Equipment	15 w/m^2	External wall U-value	0.18 (W/m^2.C)	Heating set-point	18°C
Lighting	12 w/m^2	Internal wall U-value	0.22 (W/m^2.C)	Cooling set- point	25°C
		Floor/ceiling U-value	0.20 (W/m^2.C)	Operating time	08:00-18:00

*Occupancy profile: the building occupied five days a week, based on the following schedule, for offices 09:00-13:00 occupied 100%, 13:00-14:00 occupied 70%, 14:00-18:00 occupied 100%. For Skycourt 09:00-18:00 occupied 100%

The ventilation strategies

The study was carried out in two ventilation manners,

1. The base case, this represents the current practice, which considers isolated mechanical heating, cooling and ventilation for the skycourt. The base model is used as a benchmark reference to compare the energy and thermal performance when other ventilation strategies are applied. See Figure 3

Skycourt is ventilated isolatable

Base Case (BC)

skycourt and adjacent offices are mechanically ventilated, heated and cooled separately

. Air change rate for offices is 3.1 ac/h at 18° C
. Air change rate for skycourt is 0.167 ac/h at 18°C

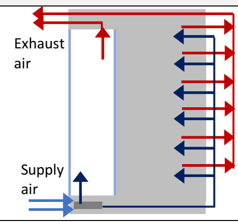

Figure 3. Proposed ventilation strategy for the base case - mode one

2. Skycourt as a buffer area that does not consume energy for heating either cooling. Five ventilation strategies are suggested to mediate the internal environment of the skycourt depending on the required fresh air for the adjacent offices as air supply or air exhaust. These combined strategies are categorised into three principles. First, skycourt is a sealed space. Second, the exhaust air from the offices mediates the skycourt. Finally, skycourt is ventilated by the supply fresh air required for the offices. Simulation is carried out to nominate the optimum approach. Figure 4 illustrates the principles, air movement and simulation settings for the proposed strategies.

Results and Discussion

The energy demand for heating and cooling of the building and the thermal comfort conditions at the occupancy level of the skycourt are taken as criteria of comparison. Thus to define the optimum ventilation strategy.

Energy performance comparison

The results obtained from the BES of the monthly heating, cooling, solar, fabric, ventilation and power loads for the skycourt are shown in Figure 5 . It is apparent from the charts that the power and solar gain are the same due to similar simulation settings.

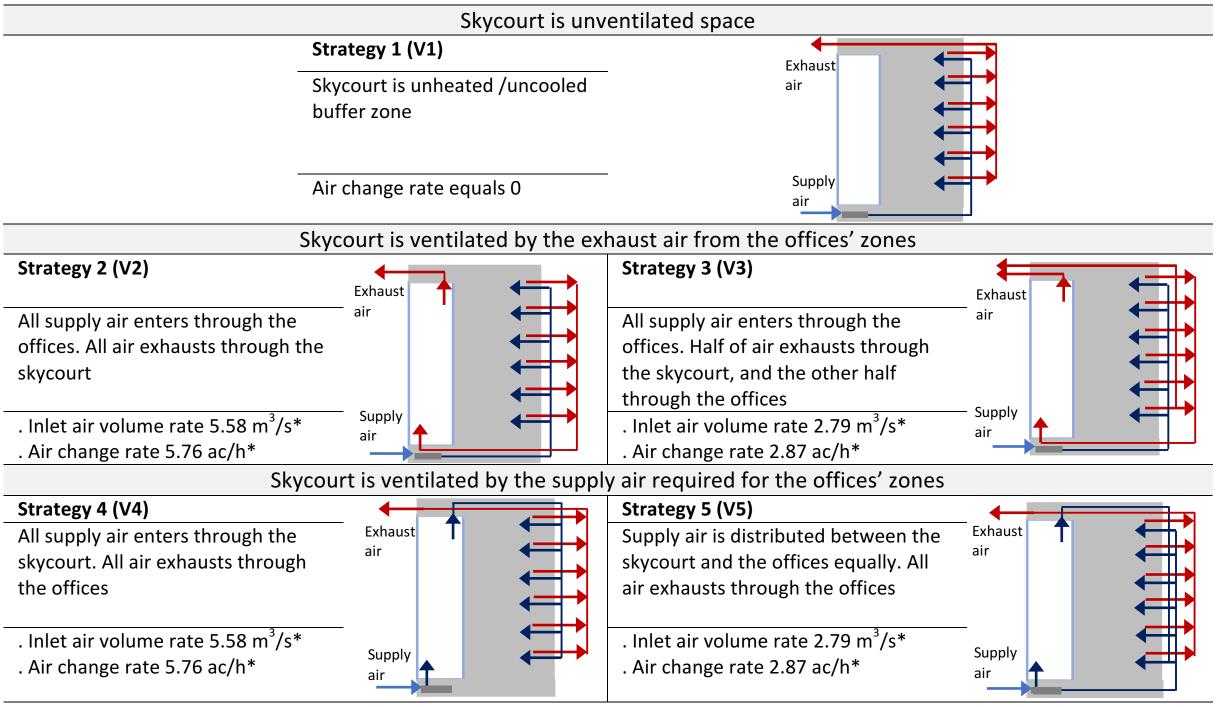

Figure 4. Proposed ventilation strategies for the skycourt for mode two

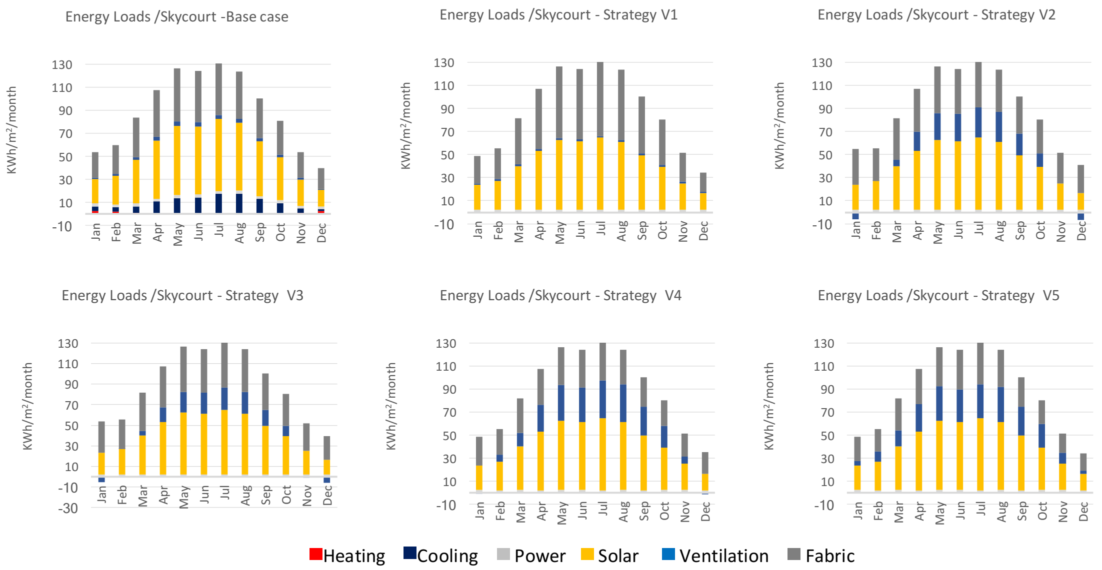

Figure 5. Results of the monthly heating, cooling, solar, fabric, ventilation and power loads for skycourt

In addition, it is seen that strategy two, three, four and five account high ventilation load due to the airflow mechanism. However, as ventilation load increases, fabric load decreases. Strategy one records the least ventilation loss by 17.94KWh/m^2/year and the highest fabric loss by 522.63 KWh/m^2/year. Strategy two and three account less ventilation load (138.83KWh/m^2/year and 117.0 KWh/m^2/year) correlated to strategy four and five (216.37 KWh/m^2/year and 227.03 KWh/m^2/year). That is due to the temperature difference of the inlet air to the skycourt. It is higher in the previous two cases. The results, as shown in Figure 6, indicate that the proposed ventilation strategies account almost 50% reduction in the total annual energy demand for heating and cooling in comparison to the base case. In strategy two, the demand is reduced from 220KWh/m^2/year to 91.9 KWh/m^2/year for each floor. Strategy four and five report higher demand than strategy one, two and three. From this figure, it is clear that less inlet airflow rate requires more heating and cooling demand. The strategies account sequentially the following demand 94.33, 91.9, 93.21, 110.05, 98.30 KWh/m^2/year.

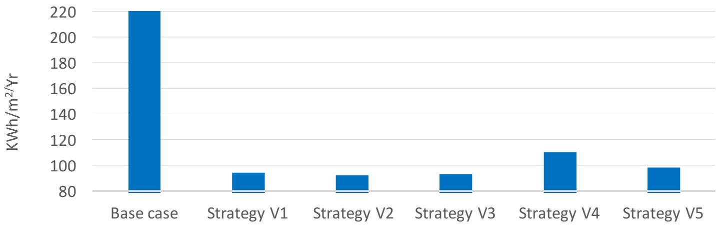

Figure 6. Results of the annual heating and cooling demand

Thermal performance of skycourt comparison

The CFD results predicting the thermal conditions -air temperature gradient (°C) and air speed (m/s) in the skycourt in several seasons are demonstrated in Figure 7. Cross-section location (A-A) is shown in Figure 2. The comfort criteria recommended by the British Council for Offices (BCO) guide (2014) is adapted to verify the thermal conditions at the occupancy level of the skycourt (air temperature ranges in summer 24°C ± 2°C, in winter 20°C ± 2°C and airspeed ranges between 0.1m/s and 0.2m/s). It is evident that the skycourt cannot be considered a thermal comfort space without inlet airflow. The indoor air temperature in summer for strategy one is very high and reaches 50°C at the hottest hour, on the other hand, it is extremely cold in winter with average 8°C at the coldest hour. In additions, the results show that the skycourt is thermally comfortable in transitional seasons. However, the indoor air quality is not satisfied.

The air temperature in the skycourt at summer when adopting strategy two ranges between 25.0°C and 32.0°C in the whole skycourt space, and about 26.0°C of 0.2m/s average air speed at the occupancy level. At the coldest hour, the temperature graduated from 14.2°C to 19.9°C with 0.3m/s. This range might not provide the required comfort degree in winter. However, it is the best temperature recorded between the proposed ventilation strategies in winter. On the other hand, reducing the airflow volume rate inside the skycourt as suggested in strategy three causes raise the air temperature in summer and decline in winter. At peak hour, the temperature increases from 25.0°C to 29.0°C of 0.14m/s, whereas at a cold hour from 12.8°C to 19.7°C of 0.36m/s airspeed. Considering the skycourt as a space for mediating the air temperature before entering the offices' zones as suggested in strategy four, accounts the most comfort conditions in summer peak time. Air temperature ranges between 23.3°C and 26.5°C and air speed records 0.22m/s. Whereas, when the external air temperature is -5.1°C, the temperature inside the skycourt ranges from 13.4°C to 17.9°C with 0.28m/s. Strategy five accounts 27.6°C to 31.5°C with 0.14m/s at summer peak hour and 11.9°C to 17.7°C with 0.32m/s at the coldest hour. The simulation at a normal hour in spring accounts the following results for the skycourt at the occupancy level; 22.7°C, 0.06m/s for strategy one, 22.1°C, 0.17m/s for strategy two, 22.0°C, 0.1m/s for strategy three, 19.0°C, 0.18m/s for strategy four and finally 18.8°C, 0.12m/s for strategy five.

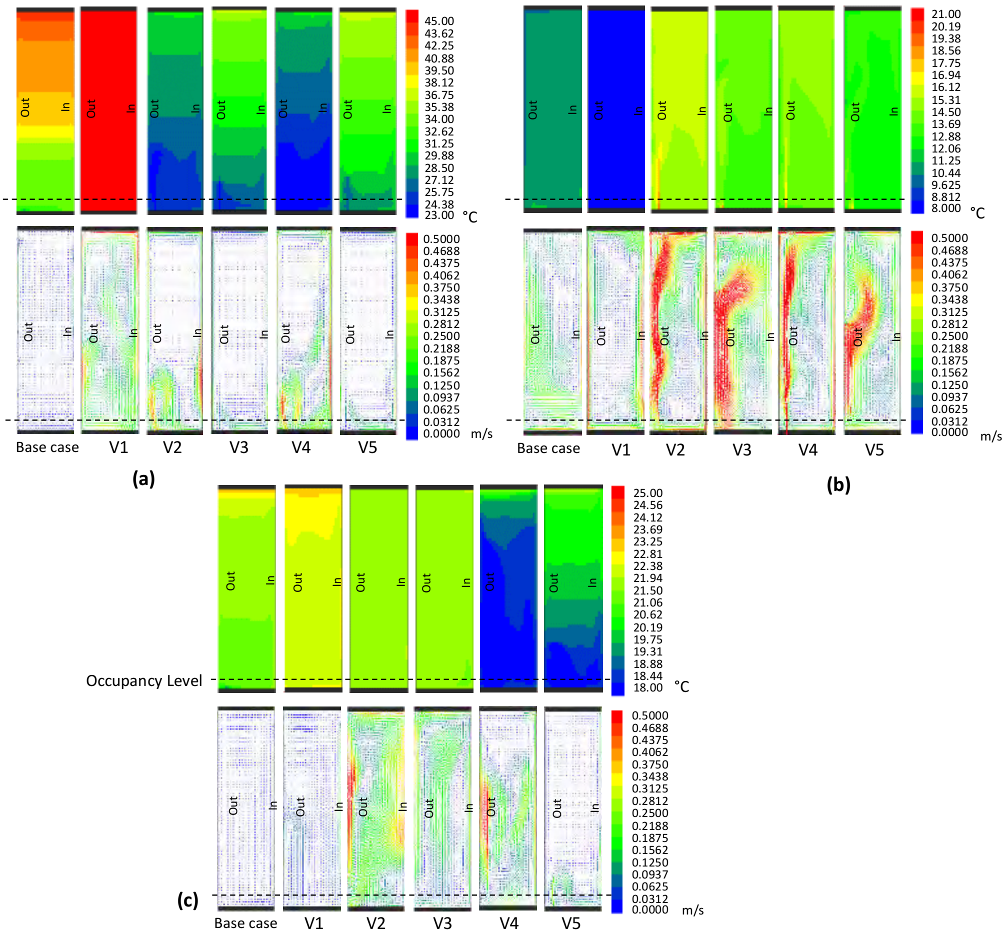

Figure 7. Results of the thermal conditions in skycourt at (a) the hottest hour in summer, (b) the coldest hour in winter and (c) the typical hour in mid-season

Discussion

The simulation results indicate that integration of skycourt in an office building as a space adopts isolated mechanical ventilation increases extremely the total energy demand significantly the cooling loads. In this case, air temperature seems to be comfortable at the occupant level of the skycourt. However, the supply air rate is considered low and might not be efficient due to the height of the skycourt. However, the simulation results highlight that the combined ventilation strategies for the skycourt show potential for energy saving and thermal comfort nevertheless differently. The findings of the study show that the optimum ventilation strategy to minimise the requirements of energy besides ensuring the thermal comfort at the skycourt is strategy two.

Conclusion

The paper has discussed the thermal and energy performance of a skycourt when incorporated as a buffer zone in an office building. Several ventilation strategies based on the concept that skycourt is a non-cooled and unheated space -does not consume energy for cooling either heating- are investigated to mediate the internal thermal conditions of the skycourt. These ventilation systems were developed depending on the required fresh air for the adjacent offices of the skycourt as air supply or air exhaust. The results indicate that a combined ventilation strategy for the skycourt enhances the energy saving for the building and provides advantages on occupants' thermal comfort. A ventilation strategy that depends on the maximum airflow volume rate exhausted from the adjacent offices to the skycourt has a significant effect on cooling the skycourt space. In addition, it can achieve about 58% heating and cooling energy saving compared with mechanical heating and cooling. Furthermore, this strategy could affect the nearby offices positively in terms of reducing heating and cooling demand and providing shading. In addition, the study found that coupling models (HTB2 and CFD-WinAir) provides an efficient prediction of the indoor environment for the skycourt.

Abstract: Natural ventilation is a passive alternative to create comfort and healthy indoor conditions. Particularly in hot humid climates, full day ventilation is the best strategy to promote thermal comfort conditions, because the increase of the airflow velocity increases the sweat evaporative cooling of the occupants. Thus, it is important to assess the indoor natural ventilation in terms of the thermal comfort. This work uses a novel method, the Heat Balance Index (HBI) to evaluate the thermal comfort of the occupants in terms of the indoor natural ventilation in hot climates. HBI gives a method to define the comfort velocity range useful to calculate the well-ventilated percentage of a space. HBI considers the metabolic heat production and the heat transfer between the body and the surrounding given by the mechanisms of radiation, convection and evaporation. The HBI is applied to a study case based on Computational Fluid Dynamics simulations of a room with a window and a windexchanger in one climate condition of a Mexican city. The study case simulations are validated with experiment results. The application example gives the percentages of the living volume with discomfort by low ventilation, with comfort by adequate ventilation and discomfort by high ventilation.

Keywords: Natural ventilation, hygrothermal comfort evaluation, CFD simulations, heat balance, hot-humid climate

Introduction

Natural ventilation is an alternative to provide comfort and healthy indoor conditions, reducing the energy consumption. Typically, the energy cost of a naturally ventilated building is 40% less than that of an air-conditioned building (EEBPP, 1993). For hot humid climates, full day ventilation is the better strategy to promote thermal comfort conditions (Liping and Hien, 2007), because the increase of the airflow velocity increases the sweat evaporative cooling of the occupants.

For ventilation performance evaluation, the most used parameters are the mean magnitude velocity at the space, U, and the concept of well-ventilated percentage of a space, P, that is defined by Bastide et al. (2006) as the percentage of the volume with velocities within a velocity range (U_{min}; U_{max}). They show that the results are very sensitive to the choice of U_{min} and U_{max}, but they do not give a methodology to select these values.

For the evaluation of thermal comfort, the most common method is the Predicted Mean Vote, PMV, with the Predicted Percentage Dissatisfied, PPD, (Fanger, 1970). This method has been developed in controlled conditions, not in natural ventilated buildings.

However, the temperature ranges of validity of the models used by all these indices do not cover the high temperatures of hot climates. There are thermal comfort models useful for non air-conditioned spaces, i.e. naturally ventilated spaces, such as adaptative comfort temperature models that are functions of the monthly mean of the outdoor air temperature (De Dear and Brager, 2002; Humphreys and Nicol, 2000; Yang, 2003). Only one study was found that proposes a method for the evaluation of natural ventilation in terms of thermal comfort (Su et al., 2009). The authors propose temperature neutrality formulas, one for indoor air temperature over 28 °C and other for indoor air temperature below 28 °C, that are functions of the monthly mean of outdoor air temperature, the relative humidity and the airflow velocity near occupants. They considered a comfort zone band width of 4 °C. Unfortunately, the authors do not give details of the methodology followed to derive these formulas.

The Heat Stress Index, HSI, is a method used to evaluate thermal comfort for indoor in hot conditions (Belding and Hatch, 1955). It is defined as the ratio of the required evaporation to the maximum evaporative capacity of the air. The Index of Thermal Stress is a method to evaluate thermal comfort for outdoors in hot climates, ITS (Givoni 1969). Also for outdoors, but for cold climates, is the windchill correction (Aynsley, 1974).

The Heat Balance Index, HBI, (Castillo and Huelsz, 2017) provides a method to define the comfort velocity range (U_{min}; U_{max}) in hot climates. The HBI is useful to calculate the well-ventilated percentage of a space. In the next section, more details of HBI are given. This paper presents an application example of the HBI to evaluate the indoor natural ventilation in hot climates in terms of the thermal comfort of the occupants. The application example is applied in a room with a window and one windexchanger by using Computational Fluid Dynamics (CFD) simulations with one weather condition of a Mexican city.

Heat Balance Index

The thermal comfort is obtained when the metabolic heat production is totally transferred to the surroundings without heat stress, the Heat Balance Index, HBI, explained here, is defined as the ratio between the comfortable heat balance of the body and the metabolic heat production (Castillo and Huelsz, 2017). The comfortable heat balance of the body is given by the algebraic sum of the metabolic heat production and the heat transfer between the body and the surrounding given by the mechanisms of radiation, convection and evaporation,

$$HBI = \frac{M - R - C - E}{M} \tag{1}$$

where M, R, C and E are the metabolic heat production, and the heat transfer by radiation, convection and evaporation, respectively, all expressed in (W/m^2). The following empirical expressions for R, C and E (Wang et al., 2011) are used,

$$R = C_1\left(T_s - T_r\right) \tag{2}$$

$$C = C_2 U^{3/5}\left(T_s - T_a\right) \tag{3}$$

$$E = C_3 U^{3/5}\left(P_s - P_a\right) \tag{4}$$

where T_s = 35 °C is the skin temperature, T_r (°C) is the mean radiant temperature, T_a (°C) is the ambient temperature, U (m/s) is the air velocity, P_a (10^2 Pa) is the partial pressure of water vapor and P_s = 56 $\times 10^2$ Pa is the vapor saturation pressure at T_s. The model constants are C_1 = 4.4 W/m^2°C and C_2 = 4.6 Ws$^{3/5}$/m$^{13/5}$°C . The factor C_3 for maximum evaporative capacity in Belding and Hatch (1955) has a constant value. In this work, the factor C_3 was modified for comfort evaporation by correlating results from the PMV comfort range (±0.5), resulting in $C_3 = 26.903 – 0.857T_a – 0.003RH$; RH where is the relative humidity. When the value of C_3 is less than zero, it is considered as zero. These expressions are based on the assumptions that all the latent heat of sweat evaporation is drawn from the body and the skin temperature, T_s = 35 °C, is constant. As the evaporation is only possible if $P_s > P_a$, if this condition is not fulfilled E = 0 in Eq. (4). Also, if the calculated value of $E < 0$, it is considered as zero. In this model the heat transfer by breathing is not considered. The heat transfer by this mechanism can represent up to 5% of the metabolic level considered in the present study (standing, light activity) and will represent a lower proportion for higher metabolic levels. As HBI is developed for hot climates, in the PMV calculation single layers of light weight clothing are considered, I_{CL} = 0.05 m^2°C/W = 0.32Clo.

In Table 1, the range of conditions covered by the empirical expressions (Eq. (2) - (4)) used for the calculation of HBI are shown. These range of conditions, based on Wang et al. (2011), allow a proper application in hot climates, as the climate studied in this paper.

Table 1. The range of conditions covered by the HBI, based on Wang et al. (2011).

Lower limit		Upper limit
65 W/m^2	≤ M ≤	327 W/m^2
21 °C	≤ T_a ≤	31 °C
0.25 m/s	≤ U ≤	10.00 m/s
0 %	≤ RH ≤	100 %
3 ×10^2 Pa	≤ P_a ≤	56 ×10^2 Pa

A zero value of HBI represents the neutral thermal condition, where the heat generated by the body (M) is exactly equal to the heat transferred to the surroundings with comfort evaporation. For this work, the range 0.2 ≤ HBI ≤ 0.2 is considered the comfort range. This range is obtained by correlating the PMV comfort range (0.5 ≤ PMV ≤ 0.5) with the HBI. HBI < 0.2 indicates that the body has an overdissipation greater than the 20%, with respect of M, causing a cold uncomfort. On the other hand, HBI > 0.2 signifies that the body has a subdissipation greater than the 20%, thus the body feels a hot uncomfort.

In order to evaluate the range for thermal comfort of the magnitude of the air velocity produced by natural ventilation, U is solved from Eq. (1) to Eq. (4),

$$U = \left[\frac{M\,(1 - HBI) - R}{C_2\,(T_s - T_a) + C_3\,(P_s - P_a)}\right]^{5/3} \tag{5}$$

As can be observed, U depends on HBI. Three magnitudes of U are distinguished: U_{min}, U_{neu} and U_{max}, for the *HBI* values of 0.2, 0.0 and 0.2, respectively. Thus $U_{min} \leq U \leq U_{max}$, represents the comfort air velocity range for a given activity (M value) and climatic conditions.

Windexchanger reference case

The windexhanger (WE) reference case has square-cross-section, one duct, four openings and flat roof. It is located on the center of a room roof. The WE has a height of 1.40 m measured from the roof, have a square-cross-section of 0.65 m in length and it is designed with a roof eave of 0.64 m as solar and rain protection. The interior dimensions of the room are W×D×H = 3.0×3.0×2.7m^3 (Fig. 1). The room has a square window at windward, 1.30 m in length, giving a wall porosity (opening area divided by wall area) of 17% (Etheridge, 2012), it is centered on the wall and its base is at a height of 0.90 m from the floor.

Experiments

The room with the WE reference case was experimentally tested by (Cruz-Salas et al., 2014) using a scaled model (1:25), as shown in Fig. 1. The scaled model was set in the test section of an open water channel (OWC) and Stereo Particle Image Velocimetry (SPIV) measurements were carried out. The OWC is 6 m long and has a test section of 1.0 $\times$ 0.315 $\times$ 0.41 m^3. The scaled model is made of transparent acrylic, with thicknesses of 6 mm for walls and room's roof, 9 mm for the floor, and 3 mm for the WE roof. The interior dimensions are $W \times D \times H$ = 12$\times$12$\times$10.8cm^3. The SPIV measurements were performed in the vertical central plane, as shown in Fig. 1b. In the OWC, an atmospheric boundary layer (open-terrain roughness profile) of a suburban area was reproduced. The mean velocity, U, and turbulence intensity, I, profiles were measured in the empty test section at the model position but without it, i.e. incident profiles. The obtained friction coefficient of the exponential law is α=0.29 and the aerodynamic roughness length z_0 is 0.06 cm (for full scale, 0.015 m). The incident profiles are used for a reliable validation study as recommended by (Blocken et al., 2008). A reference mean wind speed U_{ref} = 0.089 m/s (for full scale, 0.062 m/s) and a reference turbulence intensity of 20% were measured at the reference height z_{ref} taken as the external height of the room h = 12.3 cm (for full scale, 3.075 m). The experiments were made in water applying the dynamic similarity with the Reynolds number $Re = U_{ref}\, z_{re}/\nu = 1.23 \times 10^4$, where ν = 8.94 $\times 10^7$ m^2/s is the kinematic viscosity at the water temperature T_w = 25 °C.

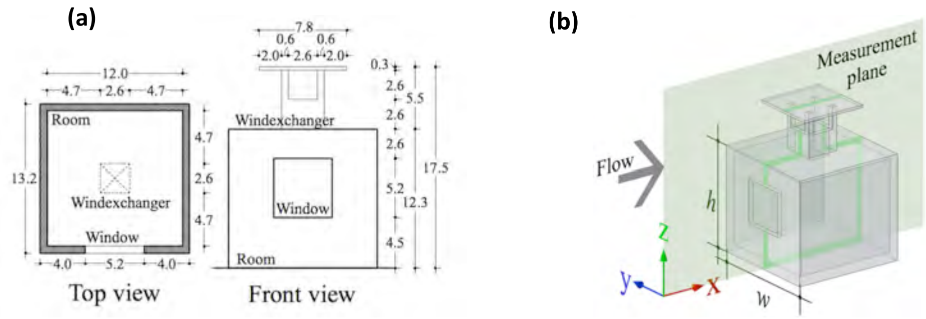

Figure 1. Model of the room with the windexchanger reference case. (a) Top and front view, units in centimeters; (b) Isometric view with the measurement plane and flow direction, where h = 0.123 m and w = 0.132 m are the external height and width of the room model, respectively.

CFD Validation

The present paper reports a CFD study performed with the commercial code COMSOL 5.1 (COMSOL 2013). This section presents the simulation model and settings for the validation of the room with the WE reference case. The settings are taken from a previous validation work (Castillo et al., 2014) using the experiments reported by (Cruz-Salas et al., 2014) and succinctly presented in previous section.

Model and settings

For the CFD simulations, the 3D steady RANS equations in combination with the shear-stress transport (SST) k-ω model are solved. The GMRES solver with MULTIGRID-SOR preconditioner is employed for velocity-pressure coupling, and the MULTIGRID-SCGS preconditioner is used for viscous terms of the governing equations (COMSOL 2013). The convergence criteria is assumed to be obtained when all the scaled residuals are equal or less than 10^{-4}.

Computational domain and grid

The computational domain with the room with the WE reference case is developed following the best guidelines by (Tominaga et al. 2008; Ramponi and Blocken 2012), its dimensions are $W_d \times L_d \times H_d$ = 0.315 × 2.346 × 0.41 m^3 (Figure 2a). A tetrahedral grid is created with 1,176,225 nodes (Figure 2b).

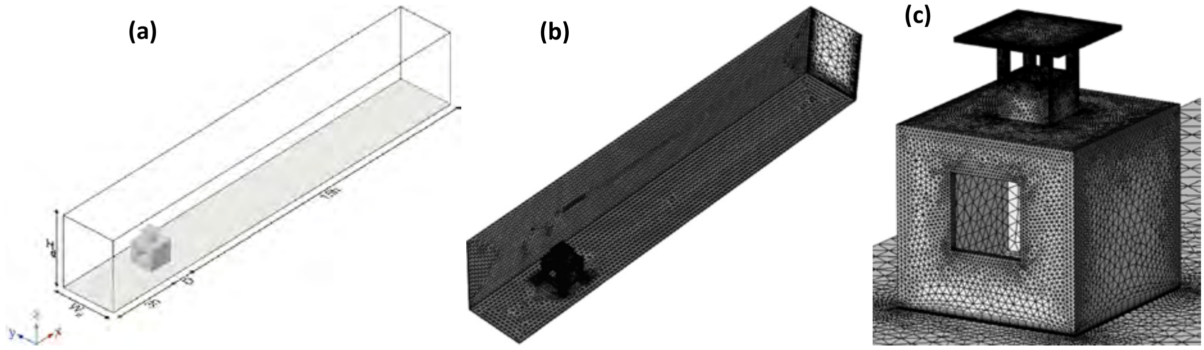

Figure 2. Computational domain with the model of the room with the WE reference case: (a) Perspective view with dimensions of the domain; (b) Perspective view of grid at bottom face (grid A with 1,176,225 nodes); (c) Isometric view of the room with the WE reference case.

Boundary conditions

The inlet boundary conditions are set according to the experimental velocity and turbulent profiles. The velocity profile is defined by the logarithmic law, $U(z) = (u^*_{ABL}/\kappa)\ln((z+z_0)/z_0)$, with the atmospheric boundary layer (ABL) friction velocity, u^*_{ABL} = 0.007 m/s, the von Karman constant, κ = 0.42, the roughness length, z_0 = 0.0005 m, and the height coordinate, z. The turbulent kinetic energy profile, $k(z) = (\sigma_u^2(z)+ \sigma_v^2(z)+ \sigma_w^2(z))/2$, is calculated from the standard deviation of each velocity component for x-direction, σ_u , for y-direction, σ_v , and for z-direction, σ_w. The turbulence dissipation rate and specific dissipation rate profiles are obtained, $\varepsilon(z) = u^{*3}_{ABL} /\kappa(z+ z_0)$ and $\omega(z) = \varepsilon (z)/C_\mu k(z)$, respectively, with the empirical constant C_μ = 0.09 (Tominaga et al. 2008). The standard wall functions (COMSOL 2013) are set at ground surface and at lateral walls. The zero static pressure is applied on the rear face of the domain. The free slip condition at the top boundary is used to simulate the air- water interface. In Fig. 3, the velocity profile and turbulent profiles, $k(z)$ and $\omega(z)$ at the inlet and incident building position in the empty domain are presented, showing that their streamwise gradients are negligible.

Validation

In Fig. 4, the experimental and CFD velocity vector fields at the central plane are shown, as well as the streamwise speed ratio, u/U_{ref}, along a horizontal line, L_h. The CFD simulations results show good agreement whit the SPIV experimental results. The averaged difference of stream-wise speed ratios is lower than 10%.

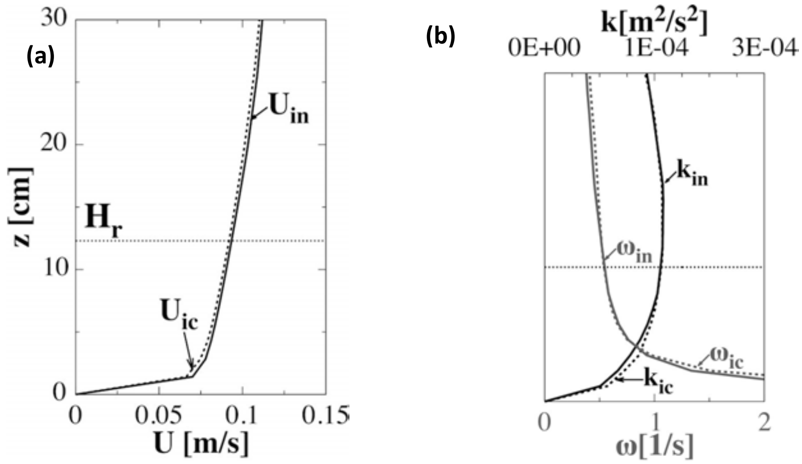

Figure 3. Vertical profiles of (left) the mean velocity, U; (right) the turbulent kinetic energy (dark line), k, and the specific dissipation rate (gray line), ω, at the inlet (continuous line) and at the incident building position (dashed line) in the empty domain. The subscripts in and ic refer to inlet and incident, respectively. The height of the model (h) is 0.123 m.

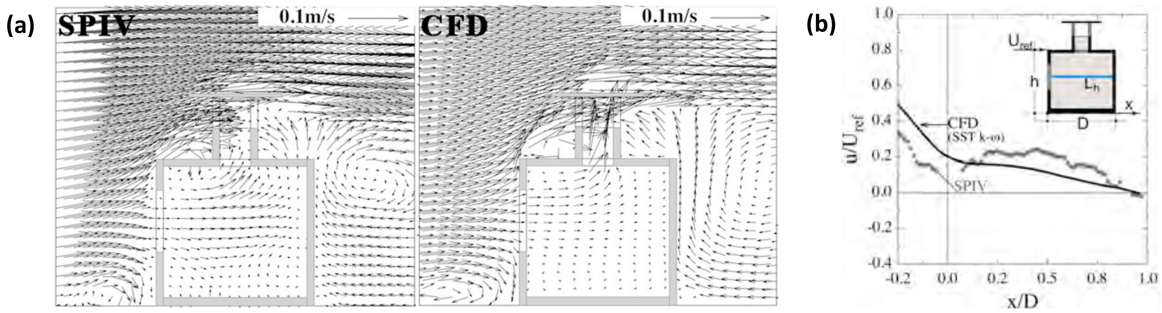

Figure 4. Experimental (SPIV) and numerical (CFD) results: (a) Velocity vector field at the central plane and (b) Streamwise speed ratio u/U_{ref} along the central line L_h.

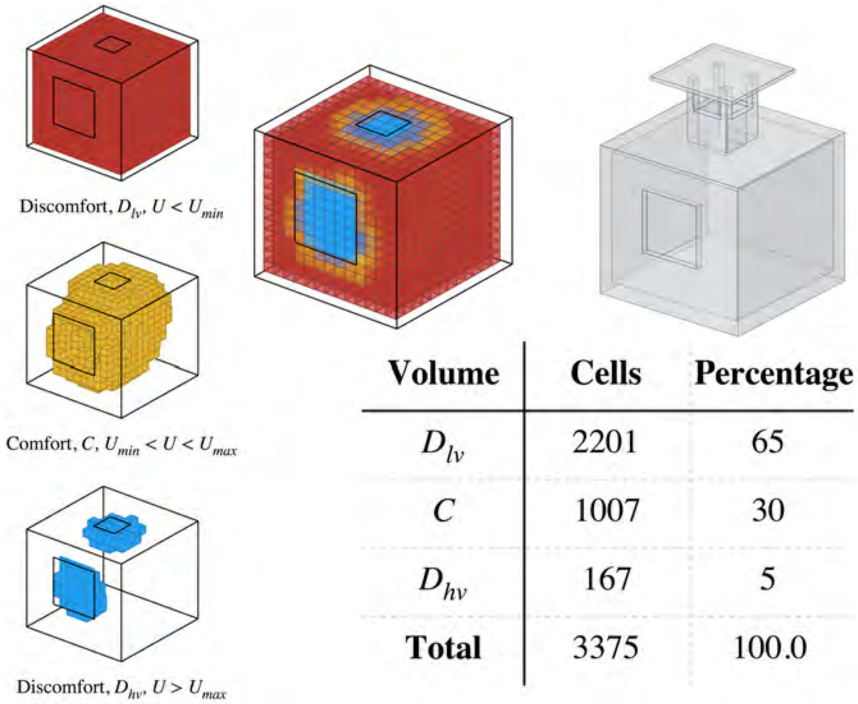
Application example of HBI

To evaluate the thermal comfort produced by natural ventilation inside the building by using the HBI, the computational parameters and settings presented in Section CFD Validation are employed. Note that, the simulations done in that section reproduces the experimental conditions, in which the building is scaled 1/25. To obtain direct results in full scale, the domain and the building are rescaled to full scale by maintaining geometric similarity. For the application example, the numerical results are averaged over the last one hundred iterations to obtain a reliable steady numerical solution of an intrinsically unsteady flow phenomena performed with a RANS turbulence model. The U_{ref} is taken from the weather data for calculating the inlet velocity profile and it is used in the kinematic similarity calculations. The interior volume is discretized in 3375 cells of which the air velocity magnitude is obtained. Then, the HBI is calculated with the following data: Radiant temperature, T_r; Ambient temperature, T_a; Relative humidity, RH; Reference air velocity, U_{ref}; and Metabolic heat production, M.

The HBI application example is performed with the averages of the maximum values of the hottest and most humid month (August) in the Temixco city located in Morelos, Mexico. These conditions are U_{ref} = 3.5 m/s (the reference air velocity at h = 2.25m building height), $T_r = T_a$ = 27 °C and RH = 80%. The $U(z)$ from the real scale are modeled as inlet boundary condition, in the validated numerical model, by applying the dynamic similarity with $Re = U_{ref} h/\nu = 6.85 \times 10^5$. Fig. 5 shows the comfort evaluation by natural ventilation of the building with a window and a windexchanger (Fig. 1), applying Eq. (5) and considering a metabolic heat production of $M = 93$ W/m^2 = 1.6 met (light activity). The interior volume can be zoned as: discomfort by low ventilation (hot discomfort), D_{lv}, comfort, C, and discomfort by high ventilation (cold discomfort), D_{hv}. In this example, the percentages of D_{lv}, C, and D_{hv} zones are 65%, 30% and 5%, respectively, indicating that for these climatic conditions the cross ventilation in this specific building is not enough to provide thermal comfort in most of the building interior.



Volume	Cells	Percentage
D_{lv}	2201	65
C	1007	30
D_{hv}	167	5
Total	3375	100.0

Figure 5. Evaluation of the comfort by natural ventilation of a building with cross ventilation. The interior volume is zoned as: discomfort by low ventilation, D_{lv}, comfort, C, and discomfort by high ventilation, D_{hv}. The range $U_{min} \leq U \leq U_{max}$ refers to the comfort air velocity range.

Discussion and conclusions

This paper provides an application example of this methodology using numerical simulations with CFD. The results of the application example only are valid for the described values of the building geometry, radiant temperature, ambient temperature, relative humidity, reference air velocity and metabolic heat production.

The HBI gives the comfort air velocity range, which is useful to calculate the well-ventilated percentage of an indoor space for a specific climate condition in hot climates and to assess the effect of a given strategy for natural ventilation. This can be done with CFD results or with experimental ones. Further research should be done to include the thermal adaptability in the HBI mathematical model.

Abstract: The supply and control of natural ventilation is essential in buildings and plays an important role in their design for hygienic reasons and for providing occupant´s hygrothermal comfort and for achieving energy savings and improving the environment. The objective of this research work was focused on the integration of experimental and Computer Fluid Dynamics (CFD) methods to visualize, measure and simulate the behaviour or natural ventilation in and around buildings aimed at providing researchers, students, and building practitioners with useful sustainable educational design tools from conceptual to documentation stages in architectural and urban projects. The methodology consisted of using physical scale models to analyse and evaluate air movement patterns experimentally. The utilization of wind tunnels provided two useful components: Visualization of airflow patterns in and around buildings and calculation of wind pressures and speeds. These two components were complemented with CFD simulations also for visualization and calculating pressures and wind velocities. The results indicated that the suitable use of experimental and CFD simulation techniques for analysis and evaluation of natural ventilation are useful tools aimed at achieving a significant reduction on energy consumption in buildings whilst improving the occupant´s hygrothermal comfort and the environment, meant to promote sustainability and to contribute to mitigate global climate change.

Keywords: Natural Ventilation, buildings, hygrothermal comfort, physical scale models, CFD, energy savings.

Introduction

At present, most modern buildings incorporate architectural styles and materials that ignore the local climatic conditions as well as its cultural and traditional factors. This is the predominant case of many contemporary buildings. As a result, such buildings are highly dependent on mechanical and electrical systems to control the indoor environment. This situation causes the consumption of large quantities of energy and thus high running costs for both artificial lighting and air-conditioning systems (HVAC), associated with problems of occupants' discomfort, both hygrothermal and visual, among others. Consequently, people who live in air-conditioning buildings have to pay huge energy bills and confront serious maintenance and economic problems during most seasons. Furthermore, those people who cannot afford to have mechanical ventilation or HVAC, their building interiors become severely unbearable and their health is seriously affected. The lack of ambient comfort conditions in commercial buildings is also a burden for people's efficiency, productivity and competitiveness and these issues are crucial for promoting and encouraging economic development. The use of energy in buildings has a direct relationship and impact on the environment; the burning of fossil fuels and their emission to the atmosphere due mainly to anthropogenic activities have provoked a severe damage in our planet.

At global level, buildings consume nearly half the annual energy for heating, cooling, water heating, and cooking, among other necessities. In terms of electricity consumption, almost seventy-five percent is used to operate and maintain buildings. Energy used in buildings comes mainly from the burning of fossil fuels, which provokes the emission of greenhouse gasses (GHG), and consequently global warming and climate change, among other consequences. The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2014) confirms and ratifies the necessity for immediate and sustainable actions to reduce the burning of fossil fuels aimed at a complete phasing out by around 2050. Buildings play an important role for this to come about, as they are responsible for almost half of the CO_2 emissions. This Report also states that it is this sector, which can be an effective turning point in the earth´s climate systems to mitigate the environmental damage, by transforming the way buildings are designed, built and operated. The approach to make this possible is by applying sustainable design in buildings by providing the required knowledge regarding its principles, concepts and methodology to implement appropriate design strategies compatible with sustainability.

One strategic area for this approach to be applied is in providing effective natural ventilation in buildings to achieve the maximum possible hygrothermal comfort conditions for the occupants at the minimal consumption of energy. The objective of this research is focused on the integration of experimental and simulated fluid dynamics techniques (CFD) in buildings, aimed at providing sustainable educational design tools for schools of architecture, and engineering, as well as design alternatives for engineers and building practitioners. Methods for evaluating natural ventilation in buildings include mathematical and computer models (CFD) as well as experimental procedures (wind tunnels). Certainly, three-dimensional physical simulators, in the form of wind tunnels are practical and useful tools for studying air movement patterns in and around buildings experimentally in architectural and urban projects. The utilization of wind tunnels can provide two components: Visualization of airflow patterns in and around buildings and measuring of wind pressures and speeds.

Natural Ventilation as an Effective Passive Cooling Technique to Provide Building Occupants with Hygrothermal Comfort Conditions

Previous studies have demonstrated that the implementation of passive cooling techniques in buildings with high thermal cooling loads is a promising alternative to contribute to solve great external and internal heat gains and high energy consumption patterns, occupants' thermal discomfort and health conditions whilst reducing environmental damage problems (Blondeau et al., DeKay, et al. 2014; García Chávez, 2015; Givoni, 1994 Santamouris et al, 1996, Lechner, 2009; Kwok et al., 2014).

Natural ventilation is one of the passive cooling techniques which can be applied as a powerful bioclimatic strategy to provide hygrothermal comfort to occupants of buildings. Natural ventilation can cool interior spaces by displacing the hot inside air with cooler outside air. This displacement can be obtained naturally by wind induced pressure or by temperature and pressure differences through the thermal stack effect. Therefore, suitable ventilation strategies in buildings can contribute to occupants' benefits in two main areas: Health and Hygrothermal Comfort. Depending on the climatic conditions and parameters as well as on occupant's comfort requirements, windows can be open throughout the night to obtain effective Nocturnal Ventilative Cooling.

In this research, natural ventilation strategies were selected for investigation applying experimental techniques in a wind tunnel and simulation CFD techniques to assess the performance of typical building configurations, aimed at providing sustainable educational design tools for schools of architecture and engineering, as well as design alternatives for engineers and building practitioners. The results of this research indicated that the suitable implementation of these techniques in the design and construction of buildings in different climates could lead to a reduction on energy consumption whilst improving the occupant´s hygrothermal comfort and the environment.

Experimental Performance of Convective Cooling on 3D Scale Models Using a Wind Tunnel

Experimental evaluation of the performance of air movement using wind tunnels have been identified its usefulness for assessments of naturally ventilated structures (Tolentino et al, 2008). This work investigated the potential of natural ventilation techniques in typical building configurations aimed at providing hygrothermal comfort conditions in building´s occupants using perplex 3D physical scale models built for visualization of air movement and measuring speeds and wind pressures (using a hot wire anemometer), and introduced in the wind tunnel (Figures 1, 2 and 3).

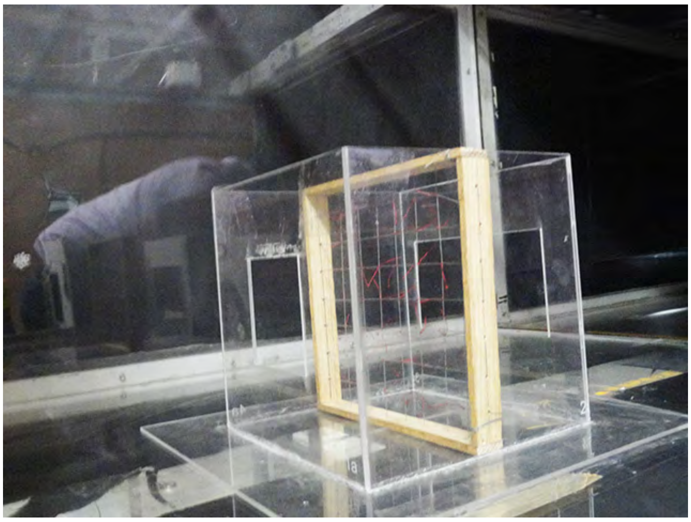

Figure 1. Visualization technique using a boundary frame with thin cords of a 3D model in the wind tunnel operating at a speed of 2 m/sec

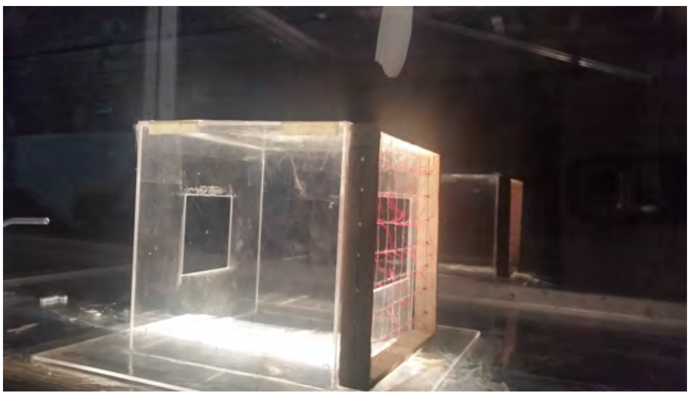

Figure 2. Visualization technique using a boundary frame with thin cords of a 3D model in the wind tunnel lit background

Figure 3. Scale 3D model for visualization technique and using a hot wire anemometer for measuring pressure and wind speed

The wind tunnel utilized for the experimental work is located at the Laboratory of Applied Thermal and Hydraulic Engineering in Mexico City. It is an open circuit wind tunnel with a suction and pressure test section. The airflow is generated by a centrifugal fan driven by a 74.6 kW (100 hp) electrical motor controlled with a variable frequency drives, to get different velocities in both test sections. The highest wind velocity in the suction test section is 65 m/s and this velocity depends of environmental conditions like temperature, barometric pressure and humidity, among other ambient factors, measured concurrently at a meteorological station in the site. The experimental equipment has a rectangular cross test section of 0.8 meters by 0.6 meters, a variable length of 4.0 meters. The wind tunnel has a settling chamber to have a good flow quality in the test section. The components are a bell mouth follow by a honeycomb grid with a cell size of 10.5 mm, thickness of 0.2 mm and a length of 85 mm. Once the flow passes through the honeycomb grid, there are five screens of 20 meshes, wire diameter of 0.23 mm and an open ratio area of 0.67, to reduce the velocity fluctuation in the test section. At the end of the settling chamber, there is a contraction with an area ratio of 9:1, a length of 1,680 mm manufactured with plywood. The flow quality in the test section was verified by measurement of velocity profile, turbulence and boundary layer in the test section using a hot wire anemometer.

Figure 4. Open circuit and suction wind tunnel used during the experiments

Methodology of the Experimental Work

During the experiments, the instrumentation used to get the velocity distribution was a constant temperature hot wire anemometer, 90C10 model. The probe 55P11 was used to measure the velocity and turbulences intensity. The probe was calibrated in a velocity range from 0.5 m/s to 50 m/s. Frequency and time sample were 30 kHz and 30 s for all measurements. The probe was moved by a three dimensional traverse system. The traverse is outside the tunnel in order to avoid the blockage effect. Pressure, temperature and humidity relative were also measured during the experiments by means of a local on-site meteorological station. Data velocities collected were reduced to get the turbulence intensity [%] in every point measured. For steady flow the turbulence intensity (Tu) was computed with the ratio of root mean square velocity and local time average velocity, shown in Equation 1.

$$Tu = \frac{u_{RMS}}{\overline{U}} \times 100 \tag{1}$$

The root mean square velocity (uRMS) in Equation 1 is shown in Equation 2:

$$u_{RMS} = \left[\frac{1}{N} \sum_{i=1}^{N} \left(U_i - \overline{U} \right)^2 \right]^{1/2} \tag{2}$$

During the first set of the experimental work, convective cross ventilation was assessed in the two scale models. Different visualization techniques were applied and subsequently pressure and wind speed were measured. A third scale model was subsequently evaluated using also visualization techniques and measurements of pressure and wind speed. This scale model included evaluation of direct wind and by means of the differences in temperature and pressure of the air, also called buoyancy or “stack effect” or “chimney effect”. The effectiveness of both convective cross ventilation and stack effect were demonstrated in the three scale models investigated (Figures 5, 6 and 7).

Figure 5. Physical 3D scale model of a real educational building for experimental assessments in the wind tunnel

Figure 6. Physical 3D scale model of a real educational building in the wind tunnel

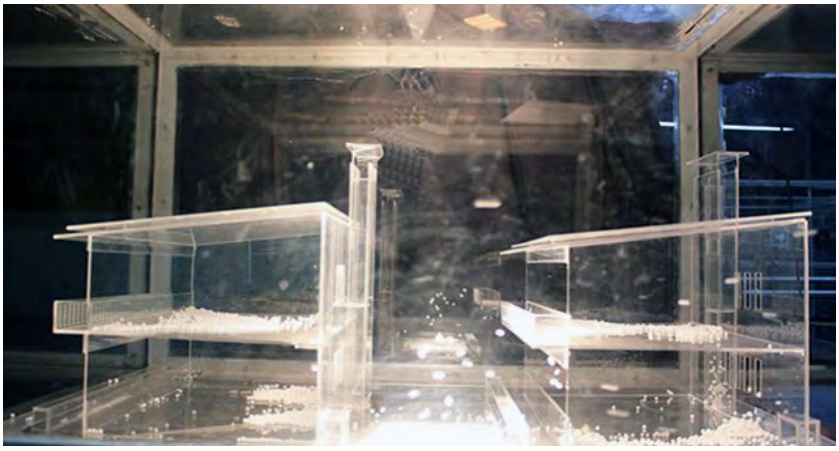

Figure 7. Physical 3D scale model of a real educational building in the wind tunnel operating, showing visualization technique of small polystyrene spheres

Air velocities and wind pressures were monitored in three measuring points located within the physical scale models at 120 cm height. Hot wire anemometers were used for the measurements in the physical model whilst maintaining the required velocity, controlled by the electronic speed system of the wind tunnel. For visualization of air patterns inside the physical model, the techniques used to identify the air movement was by means of a a) Section frame with thin wires; b) Small polystyrene spheres; and c) Smoke flux fine at different heights to provide a complete scan of the scale models. High resolution digital video and fixed pictures were applied to capture air movement pattern images (Figures 5 and 6). C to 23 ° C; the relative humidity varied from 62% to 63%, and the atmospheric pressure was stable at 79.8 kPa. The indoor air speeds within the model were measured as a percentage, relative to the external wind velocity at window level. Since the physical model tested has no curved surfaces, the air flux was discharged from the borderlines and thereby the results became independent of the Reynolds Number. Then, this outcome is a valid approximation, as the comparisons of velocity percentages of the models evaluated relative to the air flux in a 1: 1 real case, and therefore, it was a reliable parameter for analogy in this research work.

Computer Fluid Dynamic Assessments and Results

CFD techniques were applied in the three models investigated in this research. The results of the CFD analysis have shown a close approximation of the performance of air movement both outside and inside the analysed models (Figures 8 and 9). In model N1 model (for cross ventilation analysis), it can be seen an increase of air velocity inside the space. In model N2, with a 2:1 ratio, i.e. greater outlet opening relative to the inlet opening, it can be observed a more uniform upwards widespread air movement useful to promote heat gains and to dissipate polluted indoor airborne particles of an architectural space, even though air velocity is not increased. In model N3 (a real school building simulated), the performance of natural ventilation and the extracted chimney thermal convective effect is clearly observed, driving exhausting indoor air (hot and/or polluted air) towards the outside, at a greater air speed, not as large as in model N1 though, significant for the conditions of this evaluation.

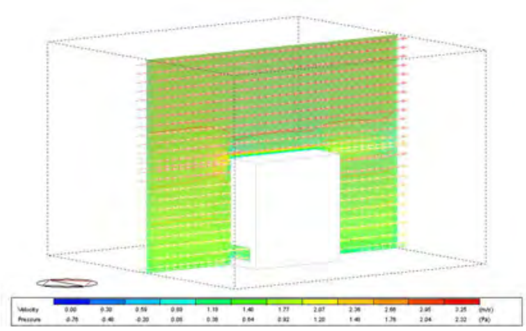

Figure 8. Model N2 Cross ventilation with Inlet (lower) and Oulet (upper) Openings. Ratio 1:2, using CFD to visualize and compute air velocity and pressure

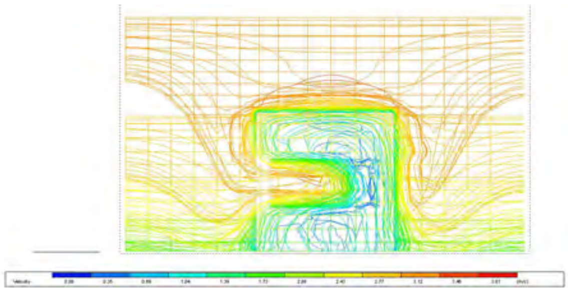

Figure 9. Model N1. Cross ventilation using CFD to visualize and compute air velocity and pressure

Conclusions

The experimental work demonstrated the benefits of using natural ventilation for providing hygrothermal comfort replicated in real buildings. When comparing the cross ventilation design alternatives with wind direction perpendicular to the façade, average percentages relative to the external wind velocities were reduced within a range from up to 21%.

It was found that when wind direction was at 45°, the air movement inside the models was optimizes, increasing an average of 36% relative to the direct cross ventilation design alternative. As to CFD simulations, this method offers researchers, architects, designers and building practitioners, an essential tool for obtaining useful information of architectural projects about the air movement behaviour inside and outside the buildings, particularly since different strategies and systems can be analysed and evaluated to optimize the design and performance of the project. Furthermore, the results can be oriented to achieve a bioclimatic and sustainable building which in turn can contribute to improve the ambient comfort conditions and health of the occupants as well as the environment and the quality of living for the present and future generations.

Abstract: This work involves experiments using subroutines developed by the author in Fortran language to calculate heat and mass transfer, and ventilation. The simulations were done to check the results of the influence of the application of different materials on a flat roof associated to passive ventilation. The target of this paper is to evaluate the use of subroutines developed to show air temperature changes, the heat transfer through a flat roof and the ventilation on a small prototype. The experiments conducted involved predictable results and that is exactly why they were suitable to check the performance of the subroutine. It is relevant to mention that the heat transfer through a flat roof was checked including a solar gain factor, which changes during the simulation using the subroutines, according to the hour of day (hourly from 7a.m. to 5p.m). The analysis started by solving the air-circulation problem to determine the wind fields, using a mixed stabilized finite element method, like Petrov-Galerkin, applied to the full Navier-Stokes equations. The thermal problem is analyzed through the SUPG – Streamline Up-wind Petrov-Galerkin stabilized finite element method. Computational simulations allow for testing low cost operational interferences before implementing a project.

Keywords: computational modelling, finite element method, indoor temperature, passive ventilation

Introduction

In this work, we resume the research in which the focus was to the development of subroutines in Fortran language, by the author, to calculate heat and mass transfer and ventilation. The test of its capacity of simulation was geared towards the small issues that can contribute with alternatives to deal with indoor heat, based on reduced, economical and environmentally friendly costs. Seeing that the city of Rio de Janeiro, Brazil, is a warm tropical climate city it is important to block the entrance of heat into buildings or at least act to minimize their input. The high costs of introducing and maintaining refrigeration systems are not only prohibitive for the majority of the population in a city such as Rio de Janeiro, but costly for the environment as well.

This hypothetical study is set in Rio de Janeiro city, where the strong heat sometimes associated with the bad location of openings in the buildings and the choice of materials can cause thermal distress. In the old areas of the city, a kind of construction called “vila” can be found, i.e., a dead end small street with only one inlet/outlet. Houses built in these “vilas” tend to lack sufficient space around them.

Besides scarce ventilation, this hypothetical model also receives solar radiation directly on its roof. The interference of incident solar radiation on a flat roof was considered; taking into account its respective materials. The thermal changes between outdoor and indoor environments include a solar gain factor related to three specific hours; 7 a.m., 12 a.m. and 4 p.m. Three openings location position were evaluated to check the best answer in terms of ventilation. In relation to the roof four scenarios were tested: cement roof's top layer in natural colour; cement roof's top layer painted in a light colour, like white. It is known that this kind of change is able to reduce heat gains besides being a cheap and easy alternative; fiber cement roof tile, formed by only one layer and fiber cement roof tile painted in white. This material (fiber cement), even not being a healthy option, is one of the most widely used materials for poor inhabitants, maybe because it is economical and easy to apply. Its application uses less wood and does not require a complex structure for its attachment.

The computational analysis started by solving the air-circulation problem to determine the wind fields, using a mixed stabilized finite element method, like Petrov-Galerkin, applied to the full Navier-Stokes equations. The thermal problem is analyzed through the SUPG – Streamline Up-wind Petrov-Galerkin stabilized finite element method.

This study presents the results of tests including both opening locations and roofing materials. The analysis of the association of both aspects, allows us to deal with the issue of keeping heat out of indoor spaces, in hot weather regions.

These results are important to understand if the subroutines in Fortran language are able to present the expected results.

Methods

The air-circulation and thermal problem are analyzed through a mixed stabilized finite element method (like Petrov-Galerkin) and the SUPG (Streamline Up-wind Petrov-Galerkin), a stabilized finite element method (Drach, 2007; 2010a). The subroutines were developed (Drach, 2007) in Fortran language and were based on the one DLearn by T.J.R. Hughes (in textbook: The Finite Element Method).

Mathematical Formulation

The problem of air circulation and heat transfer was modelling through mass, momentum and energy conservation equations. Assuming incompressibility, the known mathematical formulation for the general problem can be written as: Find $\mathbf{u}$, p and θ satisfying the following system,

$$div\ (\mathbf{u}) = 0,\ \text{in}\ \Omega\times[0,\mathrm{T}], \tag{1}$$

$$\rho\frac{\partial\mathbf{u}}{\partial \mathrm{t}} + \rho\ (\nabla\mathbf{u})\mathbf{u}\ \text{-}\ 2\mu\ div\ \varepsilon\ (\mathbf{u}) + \nabla \mathrm{p} + \rho\mathbf{g}\beta(\theta-\theta_\infty) = 0,\ \text{in}\ \ \Omega\times\left[0,\mathrm{T}\right], \tag{2}$$

$$\rho c_p\frac{\partial\theta}{\partial t} + \rho c_p\mathbf{u}.\left(\nabla\theta\right) - k\ div\ \nabla\theta = 0,\ \text{in}\ \ \Omega\times\left[0,\mathrm{T}\right]\ , \tag{3}$$

$\nabla\mathbf{u}.\vec{\mathbf{n}} = 0$ in $\Gamma_v\times\left[0,\mathrm{T}\right]$, $\mathbf{u}(\mathbf{x},\mathrm{t}) = \bar{\mathbf{u}}(\mathbf{x},\mathrm{t})$ in $\Gamma_u\times\left[0,\mathrm{T}\right]$, $\mathbf{u}(\mathbf{x},0)=\mathbf{u}_0$ in $\Omega\times\left[0,\mathrm{T}\right]$, $k\nabla\theta.\vec{\mathbf{n}} = 0$ in $\Gamma_d\times\left[0,\mathrm{T}\right]$, $\theta(\mathbf{x},t) = \bar{\theta}$ in $\Gamma_c\times\left[0,\mathrm{T}\right]$ and $\theta(\mathbf{x},0) = \theta_o(\mathbf{x})$ in Ω.

where: $\mathbf{u} = (\mathbf{x},t)$ is the velocity vector, p $=(\mathbf{x},t)$ is the pressure, $\theta = \theta(\mathbf{x},t)$ is the temperature, μ is the viscosity, ρ is the density, k is the thermal condutivity, θ_∞ is the reference temperature, $\vec{\mathbf{n}}$ is the normal vector, c_p is the specific heat, β is the coefficient of thermal expansion, $\mathbf{g}$ is the gravity vector, $\varepsilon(\mathbf{u}) = \frac{1}{2}\left(\nabla\mathbf{u} + \nabla\mathbf{u}^T\right)$ and Ω is the bounded domain with boundary $\Gamma = \Gamma_u \cup \Gamma_v = \Gamma_c \cup \Gamma_d$ with $\Gamma_u \cap \Gamma_v = \Gamma_c \cap \Gamma_d = \varnothing$ and the time $t \in [0,\mathrm{T}]$.

The term $\rho\mathbf{g}\beta(\theta - \theta_\infty)$ allows the coupling of the air circulation and the heat transfer problems.

Methods

For the air circulation problem, the numerical solutions are here obtained by a stabilized mixed finite element method, Petrov-Galerkin type method (Franca and Frey, 1992), as in Drach (2007; 2010). This method allows us to deal with the difficulties that come from the first equation system, Equations (1) and (2): the difficulty in constructing approximation spaces for problems with internal constraint; non–linearities of the convective type and numerical instabilities when advection effects are dominant. In the case of a heat transfer problem a stabilized finite element method was implemented – Streamline Up-wind Petrov-Galerkin -SUPG (Brooks and Hughes, 1982).

Simulations

A 2D computational approach was used in this work, but it can be extended to a 3D-by-layers scheme and also to a 3D full approximation, since the mathematical formulation poses no restriction to any dimension (Drach, 2010).

The prototype, here, is a module built in a narrow street. This kind of construction was very common, in the beginning of the 20th century, in Rio de Janeiro city. These houses are usually very small and have no space around them. Besides insufficient ventilation, this hypothetical model receives solar radiation directly, so the interference of incident solar radiation on a flat roof was also considered in the model, taking into account its respective materials (Figure 1).

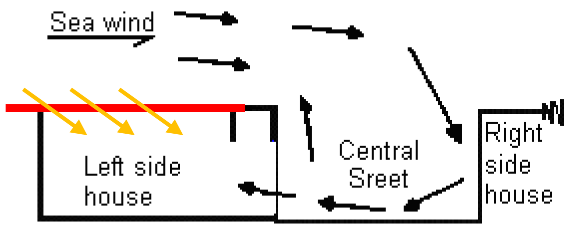

Figure 1. Prototype and the narrow street.

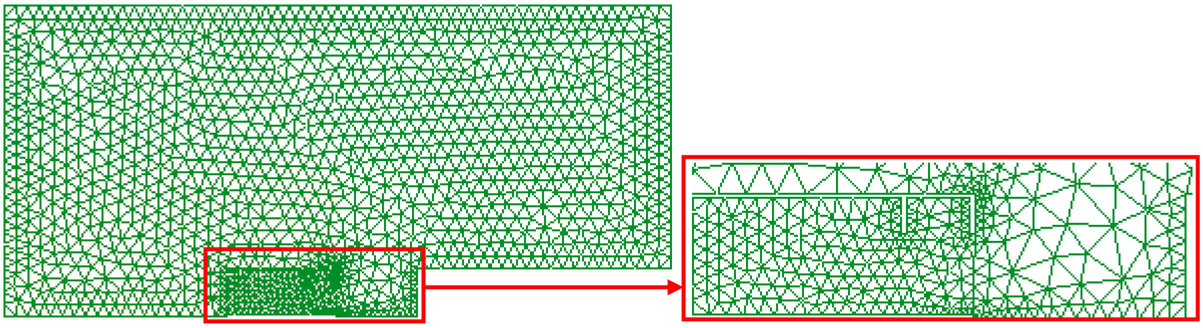
The model used deals with ventilation within openings and closed spaces, with possible leakage not being considered. The meshes generated for the experiments were composed by linear triangular elements which have collective dimensions that comprise areas bigger than the ones in the plants (Figure 2). The boundary conditions are imposed on their borders, so, the velocities and the temperatures at the entrances are considered to be unknowns and could be determined by the solution of the problem. In Figure 2, mesh and its detail can be observed.



a) b)

Figure 2. Original project whole mesh (a) and its details (b).

Boundary and initial conditions

The boundary conditions adopted for outdoor wind were 1 m/s, in order to make possible to test the situation for low velocity of air. This wind velocity corresponds to a breeze, according to the Beaufort scale, used in time forecast, and reflects the worst condition for ventilation in hot tropical climate. For the initial conditions was selected the outdoor temperature of 29ºC corresponding approximately to the average temperature in March in Rio de Janeiro city (Instituto Nacional de Meteorologia – INMET). For indoor temperature, 31ºC was considered the standard temperature. The sketch in Figure 3 shows the boundary and initial conditions adopted. The arrow on the figure top indicates outdoor wind direction and intensity. The same conditions were imposed to all experiments to make it possible to compare them (Drach, 2010b; 2011).

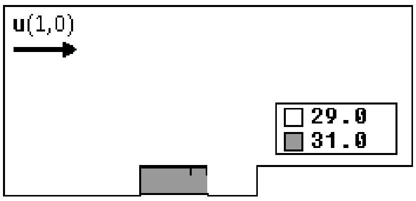


Figure 3. Boundary and initial conditions adopted for the experiments.

Solar radiation

To take into account the interference of the incident solar radiation and of the roof material on indoor temperatures, a temperature value was prescribed for the roof's surface outline that was defined based on the studies of Frota and Shiffer (Frota and Shiffer, 1988) and adopted previously in Drach (Drach, 2007). The calculation of the thermal flux intensity was made by the equation:

$q = K(t_e + \frac{\alpha Ig}{h_e} - t_i)$, where K is the global coefficient of thermal transmission, t_e is the outdoor temperature, t_i is the indoor temperature, α is the solar absorption coefficient of the material and h_e is the coefficient of superficial thermal conduction. Ig is the global intensity of incident solar radiation, with values that are fixed and related to the location, position and schedule. The solar earnings were represented by the term $\frac{K\alpha Ig}{h_e}$ and the factor of solar earnings by: $\frac{K\alpha}{h_e}$. The coefficient of superficial thermal conductance (h_e) values were adapted from Frota and Shiffer (Frota and Shiffer, 1988) and their fixed values take into account whether the walls position (vertical or horizontal) and, still, whether the flow (ascending or descending). The construction of the global coefficient of thermal transmission was also in agreement with that one given by Frota and Shiffer (Frota and Shiffer, 1988).

$\frac{1}{K} = \frac{1}{h_e} + \sum_{j=1}^{n} \frac{l_j}{k_j} + \frac{1}{h_i}$, where 1/ h_e and 1/ h_i are the outdoor and indoor superficial thermal resistances, respectively. For the case of walls composed by different materials, to each wall thickness (l) the thermal conductivity (k) of the respective material is associated and, j = 1…n, being n the number of materials of which the wall is composed.

The equations of the heat transfer through the flat roof were coupled to the subroutine developed. During the simulation process, the global intensity of incident solar radiation (Ig) was changed according to the day hour (hourly from 7a.m. to 5p.m).

Materials

For the experiment, construction materials that are common in Brazil were adopted, with the intention of checking if it would be possible to choose the one which impairs heat gains, more efficiently. The original test was done with cement roof's top layer in natural colour. The first change proposed was to paint the cement roof's top layer with a light colour, such as white. It is known that this kind of change is able to reduce heat gains and is also a cheap and easy alternative. On the third experiment, the adoption of fibre cement, formed by only one layer, was tested. Finally, the fourth test was done by painting in white the fiber cement roof tile (Drach, 2011). This material is one of the most widely used materials for poor inhabitants, maybe because it is cheap and easy to apply. Its application uses less wood and does not require a complex structure for attachment. Table 1 presents the layers that form the four covering tested, and Figure 4 shows the layers.

Table 1. The layers that form the four roofs tested.

Layer	Cement roof 1 Material – CR1	Cement roof 2 Material – CR2	Fiber cement roof 1 Material – FCR1	Fiber cement roof 2 Material – FCR2
l1	dark waterproof (no paint)	light waterproof paint	--------	light waterproof paint

l4	painted roughcast	painted roughcast	--------	--------

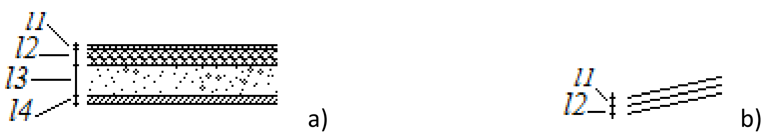

Figure 4. Layers that form the cement roofs; (a) first and second experiments, (b) third and fourth.

Using light colours to paint the roof can be one of the cheapest solution to decrease the heat transfer.

Opennings

Four configurations were checked: one without cross ventilation (WO) and three others introducing cross ventilation - low (LO), high (HO) and middle (MO) opening - in order to find the coolest scenario.

Results and Discussion

Ventilation

The results for ventilation are presented in velocity vectors and in terms of contour fill of |**u**| in a colour scale (Table 2) for each opening's configuration.

Table 2. Results presented in terms of velocity wind field: a) WO, b) LO, c) HO and d) MO.

	(a) WO	(b) LO	(c) HO	(d) MO	
Wind Field - *Vector*					Contour fill of |**u**|					

From the images (Table 2), it is possible to observe the interference of the opening location in wind field. The scenario without cross ventilation, as expected, presents the poor ventilation inside the module. The introdution of openings in a cross ventilation way, as in Drach (2010b), was able to increase indoor ventilation through all experiments. The introduction of Low Openning – LO promotes an intensification of air circulation. MO presents better distribution, if compared with LO and HO. The results presented in MO show a light tone which resulted in the occupation of 'more than half' of the internal space of the module.

Air Temperature

The thermal changes between outdoor and indoor environments include a solar gain factor related to two specific hours; 12 a.m. (Table 3) and 4 p.m. (Table 5).

Table 3. Results presented in terms of air temperature at 12 p.m.: a) WO, b) LO, c) HO and d) MO.

	(a) WO	(b) LO	(c) HO	(d) MO	**Scale**
CR1					Air Temperature - °C
CR2					FCR1					
FCR2					

The results related to midday present temperatures above 47 °C near the ceiling. Originally, the buildings in these regions had a much higher ceiling, which caused these temperatures to be further away from the occupants. Today, in houses covered by cement or fibre cement, we can clearly feel the difference in temperature as one approaches the low ceiling. The introduction of ventilation openings (LO and HO) helps to minimize the heat near the ceiling and favours the indoor cooling, as can be seen on iso-surfaces (Table 3).

Table 3. Results presented in terms of iso-surfaces at 12 p.m.: a) WO, b) LO, c) HO and d) MO.

	(a) WO	(b) LO	(c) HO	(d) MO	**Scale**
CR1					Air Temperature - °C 

The lines on the iso-surfaces, in the space without openings, show that the indoor space presents high temperatures. The introduction of ventilation, in the three forms proposed, reduces the temperature at the occupant's level.

Table 4. Results presented in terms of air temperature at 4 p.m.: a) WO, b) LO, c) HO and d) MO.

	(a) WO	(b) LO	(c) HO	(d) MO	**Scale**
CR1					Air Temperature °C
CR2					FCR1					
FCR2					

The results in CR1 and CR2 show the effect of the light-coloured paint in minimizing the absorption of heat and therefore its transference to the room. In addition, the use of ventilation makes an important contribution to promoting even greater cooling indoors.

The results in FCR1 reach high levels of thermal stress, which can be observed in practice. The presence of light-coloured paint in FCR2 indicates a reduction of indoor temperature, as well as of the area close to the ceiling.

The introduction of openings, even small ones, in low and high positions, is able to promote an increase in ventilation in a passive way. The introduction of cross-ventilation in small spaces can help us in project decisions. This strategy is particularly useful when dealing with the lack of space around the buildings in hot-climate regions.

Conclusions

The simulation results were able:

- to give expected results for the heat transfer on flat roof take into account materials;
- to show the interference of the locations of the openings on ventilation consequently on the air temperature;
- to change the variation of the global intensity of incident solar radiation (Ig) during the simulation process according to the day hour (hourly from 7am. to 5pm).

The possibility to deal with the variation of solar radiation during the simulation is a way to have results closer to what is observed in loco, as each step in the simulation takes into account the previous one.

In all the experiments, the expected changes in the ventilation and temperature fields were observed, which might indicate that the subroutines used were indeed able to show the dynamics of temperature and ventilation.

The following stage of this study will deal with the changes of wind direction during the simulation process.

CFD for Reliable Wind-Driven Natural Ventilation Studies in the Built-Environment; the Process Demystified

Bakr Gomaa[1]

[1] Architectural Engineering and Environmental Design Department, Arab Academy for Science, Technology, and Maritime Transport, Alexandria, Egypt. b.gomaa@aast.edu

Abstract: Natural ventilation in the built environment is a promising field with great potential in improving IEQ, as well as indoor and outdoor thermal comfort. For a long time, CFD has been used as an invaluable tool for exploring the mutual impact between the built-environment and air flow. On the other hand, uncertainties of the tool such as the impact of mesh quality, turbulence models, velocity profiles, and convergence criteria on the accuracy of results cloud its precision. A number of articles have discussed such problems, and in the process, they have profiled the constraints that mark the criteria of a reliable computer simulation. While such constraints establish the scientific rigor required; they add to the complexity of CFD and may cause hindrance to research development. This paper reviews previous research to demystify the process of running a scientifically reliable CFD simulations especially for wind-driven ventilation in the built-environment. To do this, we explore the literature and through a case study simulation of a box building each step is investigated and results are used to define the cross-ventilation potential across the corners of the box.

Keywords: Wind driven, Natural Ventilation, CFD, Process, Cross Ventilation

Introduction

Ventilation in buildings is the process of creating certain conditions for cooling, and/or enhanced air quality. Minimum air replacement rates can aid remove internal heat gains, and indoor pollutants (Irving et al., 2014). While ventilation can be mechanical, natural ventilation is the green alternative, that can utilize wind (pressure difference), and/or buoyancy (conductive) to drive air movement (Irving et al., 2014).

Computational Fluid Dynamics (CFD) software is one way of investigating air flow in and around buildings. The software conducts numerical analysis for the problem defined by the user. Their results are then heavily dependent on users' accuracy, rigor and understanding of the problem. This is understandably a place of great concern for scientific value of CFD use especially in scientific advancement.

Many articles have discussed simulation guidelines and tips, and in many cases the entire process is neglected. It is then our objective to define the correct procedure of a scientifically accurate CFD simulation. To do this, literature is explored to formulate the phases of a CFD simulation, and the different variables required. The paper concludes in a case study application in which CFD simulation is used to identify the cross-ventilation potential across the corners of a box building.

CFD: The Process

A CFD simulation process comprises of six main phases; definition of simulation variables(s), identification of the problem characteristics, model and mesh design, simulation, validation and finally results analysis. Figure 1

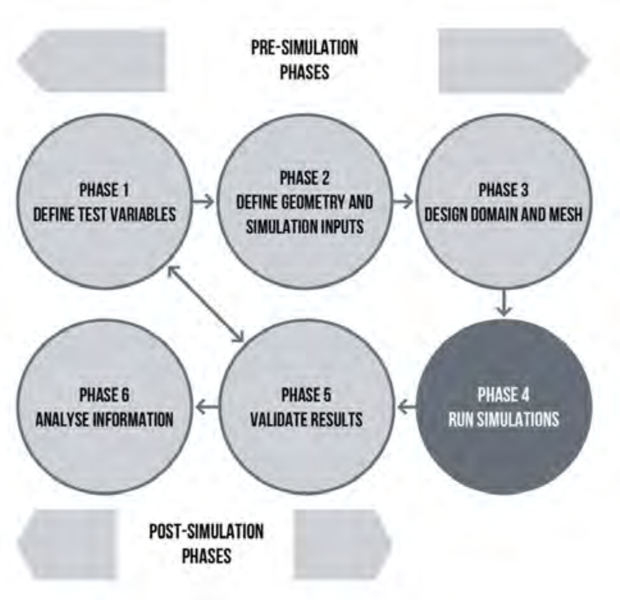

Figure 1. Phases of a CFD simulation

Phase 5 of the process -validation of results- also initiates the study as it defines the first two phases of the process. According to (Oberkampf and Trucano, 2002) validation is the comparison of simulation results against results from other sources to ensure accuracy. It is then important that CFD results are comparable to either real life measurements or wind tunnel test (Lirola et al., 2017). Successful validation/comparison of CFD results to experimental work then requires the use of nearly similar characteristics across the test and the simulation (e.g., building geometry).

Based on the first two phases of the study; the user can then design the suitable domain and mesh. The domain is the volume that surrounds the model, while the mesh is the subdivision of the model and domain into a number of small volumes. Both define the extent in which the computer would later conduct the numerical calculations (2006).

Simulation run is the fourth phase in which the machine actually conducts the numerical calculations. Such phase should terminate into 'convergence' where the final results reach a satisfactory level of accuracy. Convergence also involves mesh independence test, in which the user ensures that the results do not change drastically with finer mesh (Roache, 1994). Post simulation the designer can validate results and conduct required analysis of information for their required purpose.

Simulation Variables

Any simulation is a representation of the fluid behaviour in or around specific boundaries governed by laws of mechanics (White, 2011). For this, in addition to the geometric characteristics of the simulated case, the CFD software user should aim to identify three important variables from the tested case; its Reynolds number (Re), vertical velocity profile, and turbulence variables.

According to (White, 2011); Re is a figure that describes the relationship between the fluid's inertial and viscose forces. It is a representation of whether the flow is turbulent or laminar, and then can be used to ensure that scaling factors between tests and simulations do not change the flow characteristics.

Air velocity is understandably a critical factor in wind driven ventilation, and is one of the main inputs of a simulation. For this input air velocity must be identified especially if it has specific vertical profile, which is very common in natural ventilation studies. It is the impact of earth's surface friction on wind velocity, and its shape will depend mainly on the urban form, its density and organization (Wieringa, 1992).

On the other hand, turbulence variables are turbulence model, turbulence quantities and vertical profile(s). A CFD software has to resolve a number of equations, such as momentum and continuity, and turbulence models are one way to simplify such equations. According to (2006), a CFD software can use one of two groups of turbulence models; Reynolds Averaged Navier-Stokes (RANS) models and Large Eddy Simulation (LES) models. The same source admits that no turbulence model is universally accepted, because each model has its benefits and drawbacks.

Different turbulence models require that the simulation designer identifies specific values for turbulence quantities. For example, the RANS Standard k-ϵ model requires user inputs for the turbulent kinetic energy (TKE), and turbulence dissipation rate (ϵ). In addition to this, it is also important to identify whether such values are variable with height, which is mainly dependent on the velocity profile discussed before.

Domain and Mesh

The domain is a volume that defines the outer limits of the computational efforts around the simulated case. It has a number of boundaries that should not interfere with the fluid flow while at the same time provide correct resemblance of the simulated environment (Ramponi and Blocken, 2012).

A 3D domain is sized in relation to the dimensions of simulated case. The cross section is sized based on the blockage of the simulated building, while the length includes the upwind region, the building(s) length, and the downwind region. Two main theories can be identified in that matter; one states that the domain edges should be a minimum of 5H (H being the maximum height of the simulated case) away from the top and sides of the model (Oliveira and Younis, 2000). Another theory showed concern about 'wide' building models that may cause severe blockage when sizing the domain width based on model height only (Blocken, 2015). The same reference recommended that a maximum of 17% blockage ratio between the domain and model width should dictate the domain cross section. For the length of the domain, both theories agree that the upwind distance can be 5H while downwind distance is 15H.

Besides sizing the domain, it is also critical to identify the nature of its boundaries for the simulation physics to be resolved correctly. Input boundaries are used as air flow source, and at which the user identifies the velocity profile, along with the turbulence model terms and profiles. Output boundaries on the other hand are critical for the calculation of flow exiting the domain. Wall boundaries are used to simulate reasonable roughness especially at the bottom of the domain (where the ground landscape is simulated). Unfortunately, common commercial CFD software is currently unable to simulate large roughness implicitly. Further studies on this can be found in (Blocken et al., 2007). Also symmetry boundaries are used when the simulation geometry and flow are symmetrical along one of the domain axis (2006).

Meshing on the other hand defines the resolution and quality of the small units in which the machine resolves that problem (2006). Resolution is a measure of cells density in critical regions of the simulation, and quality is a matter of cells shape and proportions. Both factors can be controlled by a technique devised in (Van Hooff and Blocken, 2010) in which the mesh is created in 2D planes and converted to 3D using a number of extrusions.

Simulation Phase

In the simulation phase, the machine runs the numerical calculations to reach convergence. The CFD solver simultaneously solves governing equations in each mesh cell in the domain and updates the different properties of fluid flow. While CFD can iterate this process for as long as the user requires, (FRANKE et al., 2010) recommended two targets to judge convergence; 1. Residuals of momentum, continuity, TKE, and supplementing turbulence variable (e.g. ϵ) drop by no less than 6, 4, 5, 4 orders of magnitude respectively. 2. User should monitor an important variable of the simulation (e.g. velocity in critical location) to ensure that it is stable and not changing with more iterations.

The CFD software then conducts 'Spatial Discretization' in which the results calculated in the cell centers are interpolated to cell face(s). Such process can be done to various accuracies based on users choice. (FRANKE et al., 2010) and others suggest that Second-Order Upwind discretization scheme is used for scientific rigor.

Another equally important factor of a successful simulation is mesh independence test. While this part of the process is related to meshing it is in fact more relevant to convergence. In the mesh independence test; the user must refine the mesh, and repeat the simulation at least three times. This is to ensure that results are not dependent on mesh resolution. Also Grid Convergence Index (GCI) devised by (Roache, 1994) provides a measure to assess the impact of mesh refinement on final results. Figure 2

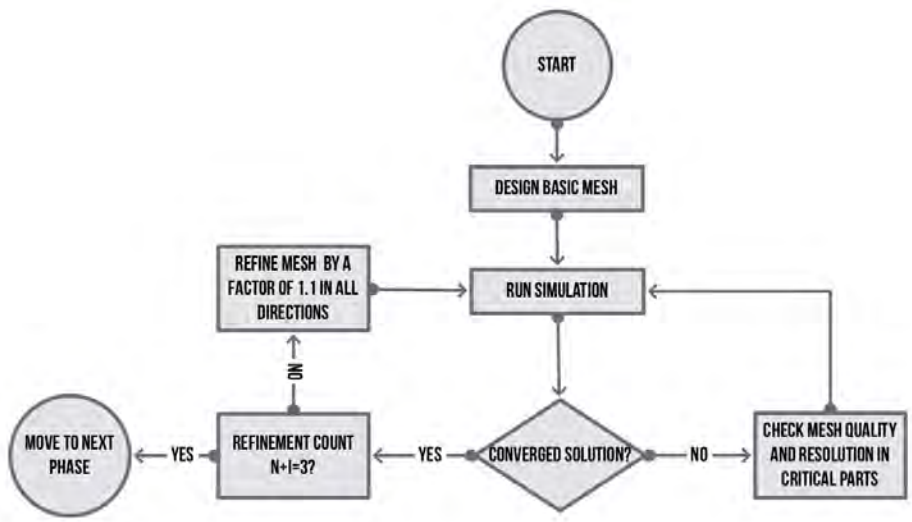

Figure 2. Flow chart showing the process of mesh independence testing

Case Study: Cross Ventilation Potential Across a Box Building

Cross ventilation in buildings is the process by which fresh air flows between two windows on opposite or adjacent walls, and is highly dependent on the pressure differential across the two openings. Cross ventilation in buildings is usually estimated using opposite windows configuration, thus it is common that ΔCp (pressure coefficient differential) between the windward and the leeward walls at central height (Irving et al., 2014) is used to define air flow due to cross ventilation. We argue that cross ventilation at the corners of buildings at different heights requires more attention and can clarify design factors that may enhance buildings design for natural ventilation (e.g., the variability of windows areas to suit the intensity of the pressure differential). Many studies such as (Ramponi and Blocken, 2012) and (Li et al., 2015) have investigated pressure coefficient patterns on simple building shapes and different settings for the general understanding of air flow, pollutants dispersion or structural loading. To the best of our knowledge, none however has defined the term CVP, nor used it to investigate the pressure differential on the buildings corners. We define CVP as the possibility of achieving specific cross ventilation conditions (Gomaa, 2016). The target of the study is then to utilise previously mentioned phases of an accurate CFD simulation on a simple box building that can then be used to identify the cross-ventilation potential across the box corners at the heights 1/3 and 2/3H.

Test and Simulation Inputs

The study is to be validated against the wind tunnel tests held in Tokyo Polytechnic University (Japan) and discussed in (Kim et al., 2012). The experimental test investigated the sheltering effect of different urban configurations compared to a standalone building. According to (Kim et al., 2012) the experiment had a Reynolds Number of 50,000 and vertical velocity profile with a log exponent of 0.2. Wind speed and turbulence intensity at building height were 7.2 m/s and 23%. For the simulation, we used Shear-stress transport (SST) k-ω model in which average speed and turbulence intensity profiles of the test were used to define the terms TKE and ω. Figure 3

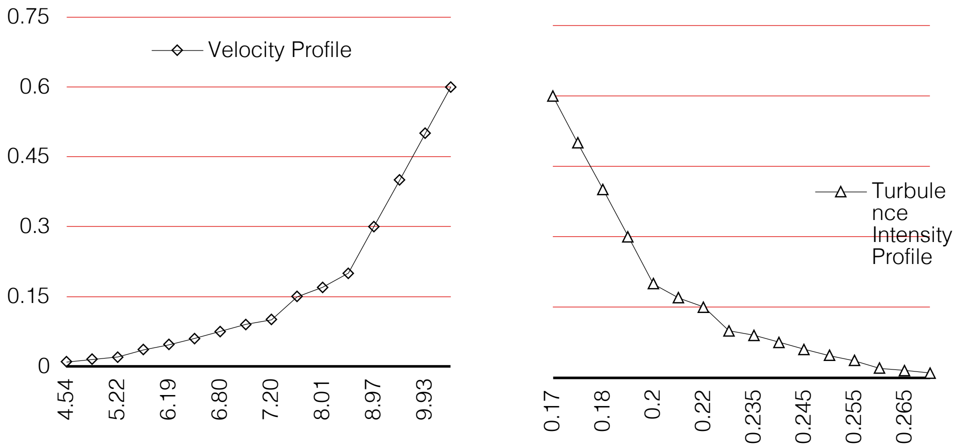

Figure 3. Velocity (left) and turbulence intensity (right) profiles used at inlet boundary of the CFD simulation after (Kim et al., 2012)

Domain and Mesh Design

Due to the small size of the case; domain sizing followed the theory of (Oliveira and Younis, 2000), however, the windward region of the domain was designed to be only 3H as indicated in (Blocken, 2015). This is to reduce the anticipated changes to the velocity and turbulence profiles due to small values of the implicit friction at the bottom of the domain. Also, only half the box building was modelled due to its symmetrical nature. Symmetry boundaries were used for the splitting edge and the side of the domain. Velocity inlet boundary was used at the inlet, pressure outlet was used at the domain end, and wall boundaries were used for the top and the bottom sides. The top of the domain however was simulated with zero friction, while the bottom had wall roughness of height of 0.0075 and roughness constant of 7. Such values had been calculated to simulate a smooth terrain (Z_0 height of 0.005) as indicated in (Wieringa, 1992).

Structured mesh was used by planning the mesh concentrations on the plan view of the domain and the edges of the box, which was then extruded twice; first to extrude mesh to building height, second extrude domain and building again to domain top. This process formed a 194,955 cells 3D mesh model. Figure 4

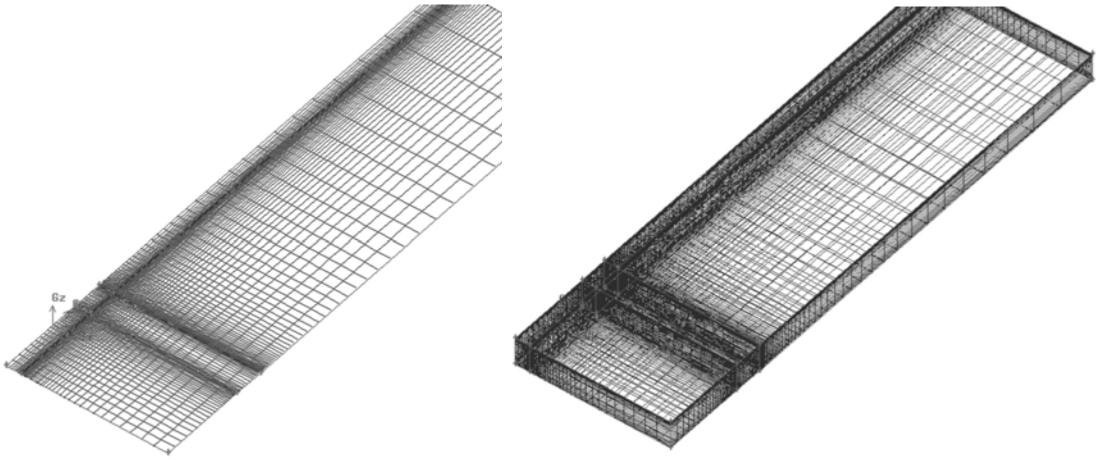

Figure 4. Left: mesh planning on the 2D level helps control grid concentrations in critical parts of the model. Right: image showing one step of the mesh extrusion in the 3rd dimension (to building height)

Simulation

The simulation was conducted using the solver Fluent 6.3; in which Pressure-Velocity coupling through SIMPLE algorithm and Second-order discretization scheme for all governing equations were utilized.

Mesh independent results were verified by coarsening initial mesh twice each at a factor of 1.1 in all directions. Roache index for the vertical pressure coefficient showed that the average discrepancy between the coarse and medium grids is 10.2% with standard deviation of 19.4. The index for the medium and fine grids on the other hand is 4.3% with standard deviation of 6.8. The largest error was for the windward edge right before the roof in which the error was 106.6 and 28.5 between the coarse-medium grids and the medium-fine grids respectively.

The comparison of the pressure coefficients across the vertical centre line of the box to test results showed a general good agreement, and excellent match at the windward side of the box. The discrepancy however was more pronounced in the separation zone at the windward edge of the roof and the back of the box. This is believed to be due to CFD uncertainties especially related to the effect of the different turbulence models. Figure 5

Cross Ventilation Potential

To define the CVP, we compared the pressure coefficient differential (ΔCp) across the corners of the building to a reference value (ΔCp_{ref}). ΔCp is calculated by subtracting the Cp values across the front and back corners at the heights 1/3H and 2/3H. Horizontally corner points lie

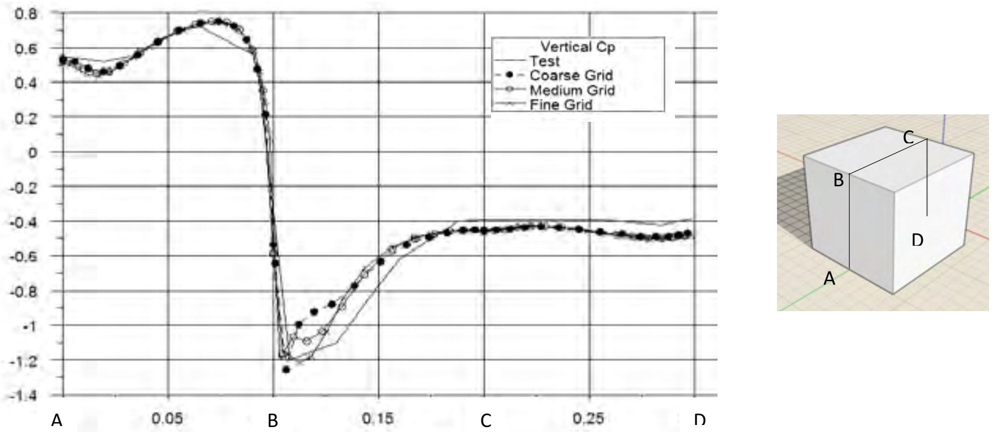

Figure 5. Vertical pressure coefficients along the centre line. Comparison between the results of different grids, and experimental test

at 1/3 building width on the windward and leeward facades, and at 1/3 and 2/3W on the side facade. Also, ΔCp_{ref} is calculated by subtracting Cp values between the front-back walls of the same building at 1/2H. Figure 6

While ΔCp_{ref} was calculated to be 1.14, ΔCp was found to be 1.45, 1.7, -0.1, and -0.07 for the top front corner, lower front corner, top back corner and lower back corner respectively. This shows that CVP is highest at the top front corner at 1.49, followed by the lower front corner at 1.27. The back corners showed very poor CVP with the values 0.088 and 0.061 for the top and lower corners respectively. Figures 6 and 7

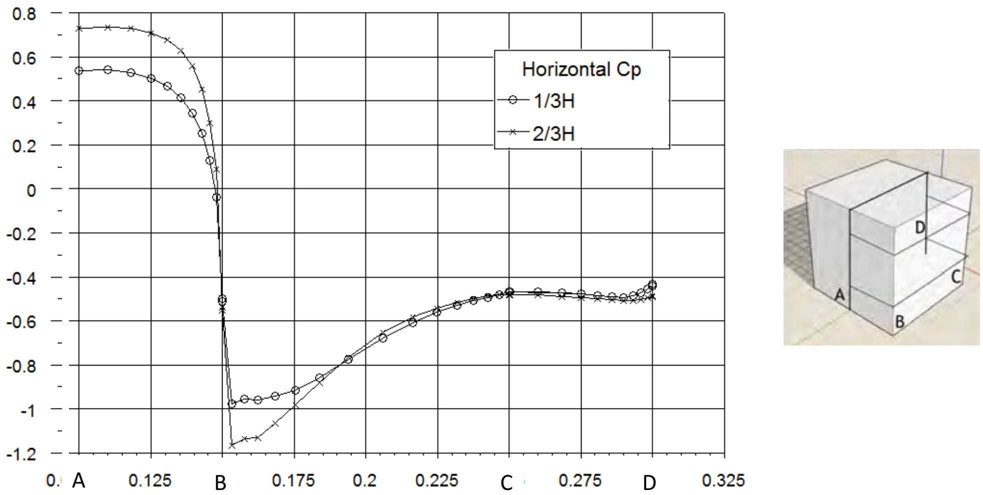

Figure 6. Horizontal pressure coefficients at the heights 1/3 and 2/3H

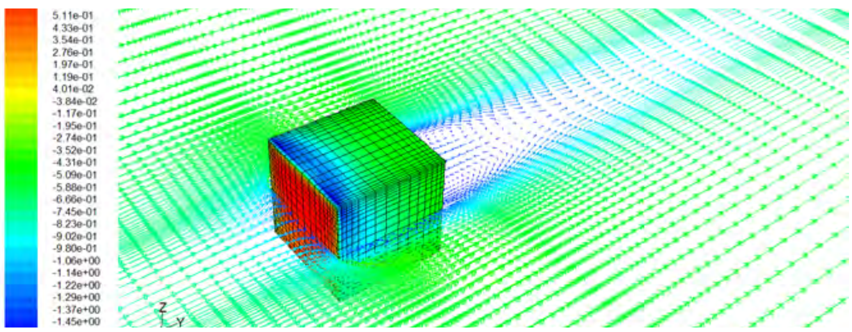

Figure 7. Pressure coefficient patterns and air flow around the box

Conclusion

This paper provides a clear path for an accurate CFD simulation. A CFD study should be supported by an experimental investigation, which defines the simulation variables. On the model level, the domain sizing must produce minimal blockage, while the mesh should be conducted with maximum control over cells concentration and quality. Also results should be checked for grid independence. For the simulation; high order discretization scheme should be used and final results compared to measurements. Based on this a case study was conducted to compare the cross-ventilation potential (CVP) between the different facades of a box building. The simulation showed that compared to CVP between the windward and leeward facades of the buildings; windward and side walls achieved higher CVP by at least 27%, while side walls and the leeward wall had lower CVP by no less than 91%.

Abstract: With large cooling potentials, natural ventilation is the main passive technique applied to tropical buildings. In computational simulations studies, the discharge coefficient (Cd) is required as a parameter to characterize the resistance the opening imposes to the airflow. As shape and angle of shading devices influence the airflow through the openings, accurate setting of Cd has a significant impact on the characterization of the cooling phenomena. This study investigates the effect of accurate Cd of five different configurations of shading devices. Using a classroom as a generic case, corrected Cd obtained from CFD models were used to simulations on the software EnergyPlus identifying airflow levels and periods of thermal comfort under the climate conditions of São Paulo. Results indicate that using 0.6 as a Cd value in the simulations is adequate for openings with shading devices that has a lower level of obstruction on the façade. However, for geometries with several slats and low angles, Cd values can be as low as 0.34. In this case, the airflow through the room decreases in average 15% in relation to the model that used usual Cd. The outcomes contribute to a more precise prediction of natural ventilation of buildings with shaded openings.

Keywords: Natural ventilation, Discharge coefficient, Shading devices, Computational fluid dynamics

Introduction

Natural ventilation is the main passive technique applied to tropical buildings compared to other design strategies. With large cooling potentials, the control of air movement through the internal environment can improve thermal comfort and indoor air quality with reduced operating costs. Building layout, size and location of apertures are relevant architectural variables to produce effective natural ventilation (Aflaki et al., 2015).

In studies on the natural ventilation in buildings, careful characterization of obstacles to the flow on the envelop, such as shading devices, is necessary to avoid inadequate assessment that can lead to large deviations between the computational predictions and the real ventilation conditions (Cruz and Viegas, 2016). The resistance the opening imposes to airflow, i.e. the quantification of the efficiency of airflow through an opening is given by the discharge coefficient (Cd). Accurate specification of Cd has a significant impact on the model capacity to describe cooling and ventilation phenomena. However, in buildings thermal performance research, some computational dynamic thermal simulation software, such as EDSL-TAS, EnergyPlus and ESP-r assume that Cd depends merely on the opening geometry (Cóstola et al., 2009), assuming generalized values.

As shape, position and angle of shading devices influence the airflow through the openings, accurate setting of Cd may have a significant impact on the software capacity in describing cooling and air changes effects of the natural ventilation. In order to investigate the effect of application of flow resistance on openings with different shading devices types and angles, this study determines accurate Cd of five different configurations of shading devices through Computational Fluid Dynamics (CFD). Using a classroom as a generic case, corrected Cd obtained from CFD models were used to simulations on the software EnergyPlus identifying airflow levels and periods of thermal comfort under the climate conditions of São Paulo city, Brazil.

Effect of the discharge coefficient on the ventilation performance

Cd is a dimensionless number that depends on the opening geometry and on the Reynolds number of the flow (Ashrae, 2013). It ranges from 0 to 1 to represent a fraction of energy to the ventilation. If Cd is close to 0, it means that the opening imposes a major loss on the energy of the airflow, while if it tends to 1, the energy loss is low. The loss is caused by friction, turbulence and it is related to air viscosity, thus, varying according to the opening´s shape and position regarding the airflow incidence and the flow path, i.e. if the air is entering or leaving the building (Cóstola et al., 2009).

Users face difficulties to accurately specify the Cd value as data available in the literature present variations. Analysing the influence of architectural parameters on the thermal performance of simulations of naturally ventilated buildings, Sorgato and Lamberts (2012) identified that Cd values vary up to 91%, which can compromise the results reliability. For instance, if Cd is estimated to be 0.6 when its real value is 0.3, the effect is the same of using an opening area of 2.00 m² when the real area is 1.00 m² (Cóstola et al., 2009).

For unidirectional non-turbulent flow caused by chimney effect, Ashrae (2013) recommends a Cd value of 0.65 and for sharp edge openings, 0.6 is the value indicated. Hult et al. (2012) recommend 0.61 as a Cd value for sharp edge rectangular openings. Tecle et al. (2013) achieved Cd values ranging from 0.65 to 1 for low-rise buildings and identified that Cd is highly dependent on the opening area and on the window to wall ratio.

When the opening has shading devices, the difficulty in defining the Cd value is even greater due to the lack of information about the diversity of shapes and sizes the shading devices can assume. There is still little information available about the effects of external shading devices for solar control on the airflow perturbation, which turns difficult the characterization of the openings and, hence, the performance evaluation of natural ventilation in buildings.

Methodology

Models description

The model used comprises of a rectangular model based on an educational building with the longest sides oriented to South/North. A classroom in the middle of the building was chosen for this study, which dimensions of 6m x 10m and 3.5m floor-to-floor height. The room presents a window opening of 20.5 m^2, positioned on the North wall (Figure 1).

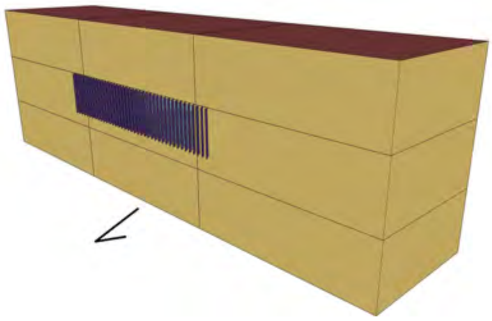

Figure 1. Building model used on the simulations

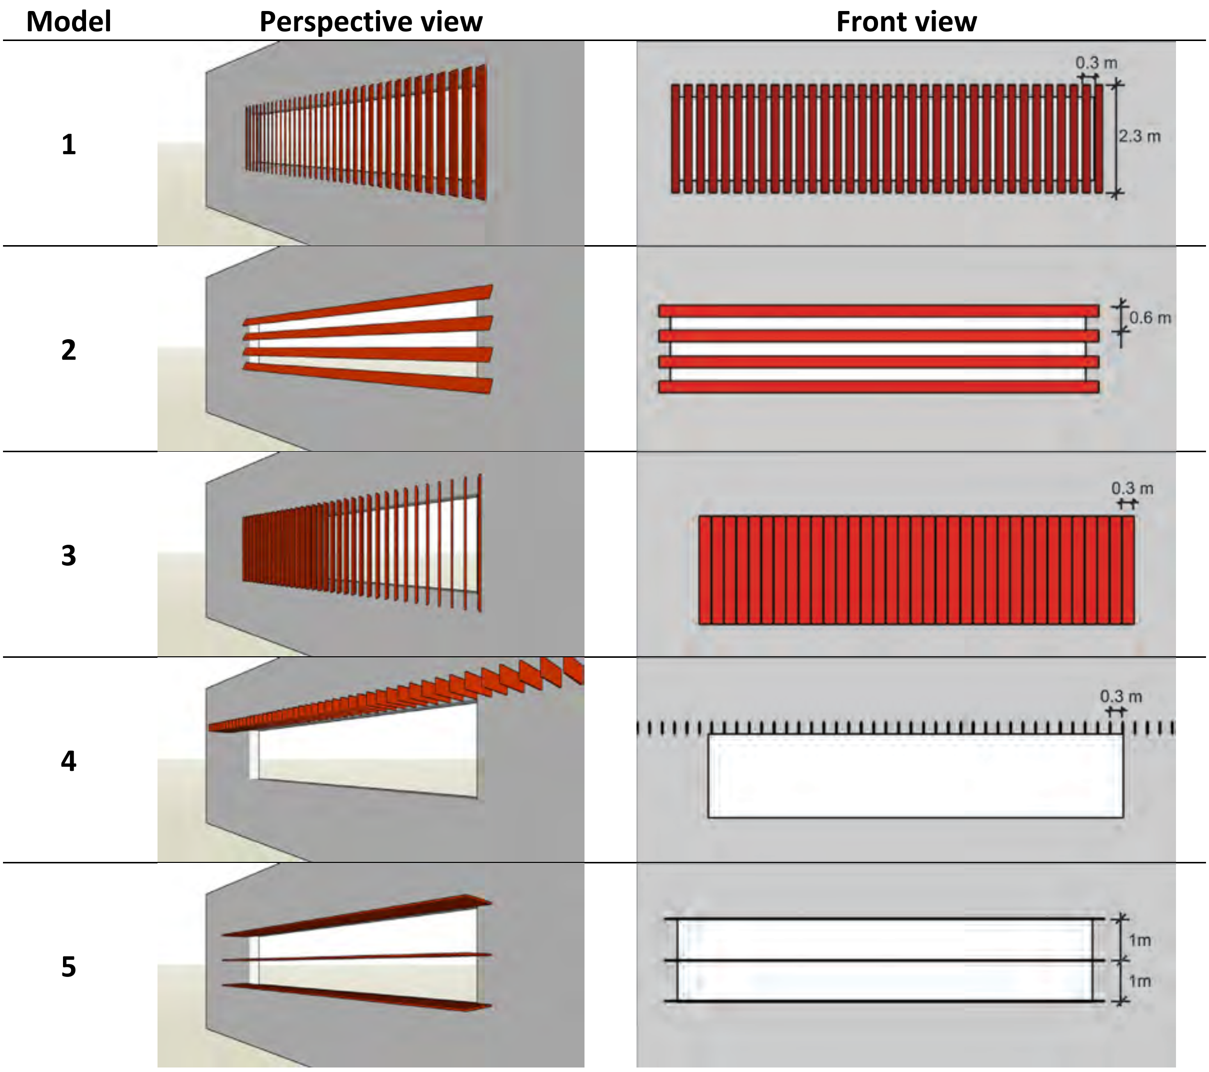

Figure 2. Shading device configurations tested

The shading devices configurations tested were obtained from a database with 30 types of brise-soleis presented by Lamberts et al. (2014), which dimensions can be modified resulting in an endless number of possibilities. Five usual shading devices were selected, as shown in Figure 2, for which the discharge coefficients were determined through CFD simulation. The values of Cd obtained in this paper were determined for unidirectional fluid flow, from exterior to the building interior.

CFD simulations

The discharge coefficients of the models tested were obtained from the CFD commercial package Ansys CFX® (version 15.0). In the CFD technique, the external atmosphere and the air space in the interior of the building are divided into domain geometries. Solid boundary layers, such as walls, ceilings, windows, are then defined and a mesh of small cells is included in the spaces, creating a grid. From that, basic fluid dynamics equations for conservation of mass, momentum and thermal energy are solved for all nodes of the grid, giving a detailed picture of the flow pattern (temperature, air velocities and pollutant distribution) in the room.

To verify consistency of the results to provide confidence in the CFD results, the models were verified based on the method used by Yang et al. (2010) in which the discharge coefficient of a window with differing degrees of opening were compared using both wind tunnel testing and CFD simulation. Yang et al. (2010) have tested opening angles of 10°, 30°, 45°, 60° and 90°, which were reproduced in the present study. The test indicated close agreement to those achieved by Yang et al (2010). To increase confidence in the results, a grid dependence test was performed through successively enhancement of the total number of elements until the Cd value did not change more than 1%.

Using steady state condition solutions, the models were set with the Shear Stress Transport turbulence model as it combines k-omega, used in the inner region of the boundary layer and the k-epsilon, specifically for planar shear layers and recirculating flows. The grid was generated by Ansys Meshing with tetrahedral elements and local refinement near to the opening and shading device was considered.

Thermal dynamic simulations

Cases with different configurations of shading devices were modelled and simulated on the EnergyPlus software. All cases were simulated under the climatic conditions of São Paulo. The weather data used is based on the test reference year (TRY) database used by the Brazilian Energy Efficiency Labelling (Inmetro, 2010). As the climatic conditions of São Paulo is characterized by mild and low temperatures, especially in the winter, the window openings control were set according to outside temperature. The opening regulator was set to start to open the North window when the outside temperature is above 16°C and modulates the degree of opening linearly until it is fully open at 20°C. The properties of the materials used on the building models and the internal heat gains profiles are specified in
Table 1.

Table 1. Characteristics of the model

Construction materials	
Ceilings	3.73 W/m^2K
Walls	1.74 W/m^2K
Use of the building	**Total gain**
Internal heat gains (People + Equipment + Lighting)	138 W/m^2

Results of thermal comfort levels are based on the standard ASHARE-55 (2013), which uses the adaptive approach to consider the indoor acceptable temperature as a function of the outdoor air temperature. With a more realistic comfort range of operative temperatures, it provides a suitable method for predicting the thermal acceptance levels of naturally ventilated buildings under tropical climate conditions.

Results and discussion

Discharge coefficients obtained from CFD simulations

Table 2 shows Cd values obtained for the different shading devices applied to the model. Results indicate that shading devices can act as a blockage to the airflow or enhance the natural ventilation depending on its configuration on the façade. Therefore, the use of a generic Cd for facades with different shading device configurations should be avoided. The lack of accurate Cd specifications may compromise the reliability of the results on the thermal performance of naturally ventilated buildings.

Table 2. Shading devices' discharge coefficients

Shading device	Discharge Coefficient
01	0.34
02	0.41
03	0.57
04	0.65
05	0.65

Cases with low angle shading devices presented the lowest Cd for both vertical and horizontal slats. For the case with slats angled 60°, the resulted Cd was slightly lower than the value commonly used, 0.6. On the other hand, cases 4 and 5, which have shading devices above the window opening and orthogonally horizontal in front of the window, respectively, resulted in similar Cd, with a value of 0.65. This indicates that the Cd value frequently used in simulation software is adequate for shading devices that has a lower level of obstruction on the façade. However, for shading geometries that works as a barrier to the flow, corrected Cd should be considered for accurate results.

Models thermal performance

Table 3 presents the daily average incident solar radiation reaching the outside North window surface. It represents the radiation incident on the window after passing through the shading devices, in each case. As expected, case 4 presented the highest level of solar radiation reaching the window as the shading device has a low level of obstruction, especially during the winter and close to midday. However, considering the high internal heat gains and the risk of glare, solar incidence is not welcome in this case. On the other hand, in case 2, the solar radiation reaching the window was 4 times lower than case 4. This is due to the suitable shading device configuration applied. Although some shading devices geometries tested are not appropriate to the room orientation, having, therefore, a great influence on the thermal comfort of the building model, this study focus on the differences in the thermal performance when corrected and usual Cds are used.

Table 3. Mean incident radiation and airflow net airflow through the window

Model	**1**	**2**	**3**	**4**	**5**
Cd	0.34	0.41	0.57	0.65	0.65
Incident radiation	113 W/m^2	42 W/m^2	96 W/m^2	168 W/m^2	90 W/m^2
Airflow	0.32 m^3/s	0.33 m^3/s	0.38 m^3/s	0.41 m^3/s	0.38 m^3/s

Table 3 also includes the annual mean of the net airflow through the window opening of the models simulated. The greatest air movement was observed on case 4, which has the lower obstructive shading device amongst the models tested. On the other hand, case 1 presented the lower airflow, as the vertical shading device with a low angle prevented the air from entering the room. In this case, the differences of airflow through the room was in average 15% between the models that used corrected and usual Cd.

Monthly totals in terms of comfortable and uncomfortable occupied hours (both due to too hot/too cold conditions) are presented for case 1, which presented the lowest correct Cd among the cases tested (Figure 3). In this case, results indicate thermal discomfort due to too hot conditions occurring in 12% of the daylight hours, being January to March the hottest periods of the year, when discomfort can reach up to 36% of the month. The model with usual Cd (0.6) applied to the window opening, resulted in 3% lower levels of too hot conditions, corresponding to 118 hours (Figure 4). The high internal gains due to the great number of people in the room and the relatively high levels of solar radiation reaching the opening can explain the moderate effect that ventilation has on the thermal comfort when comparing cases using corrected and usual Cd.

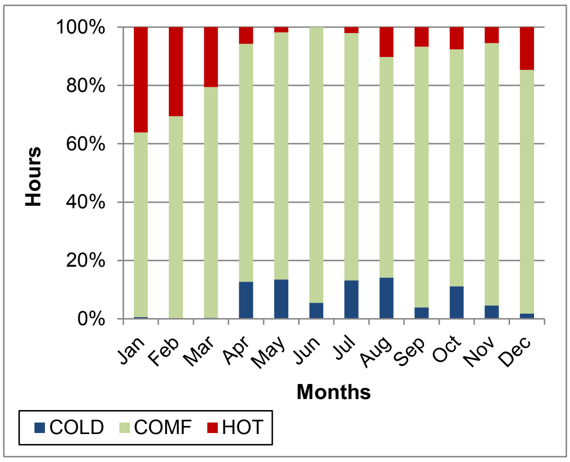

Figure 3. Hourly thermal acceptance of model 1 with corrected Cd (0.34)

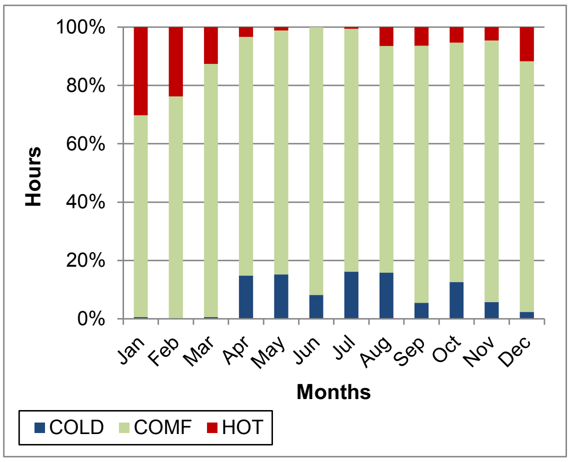

Figure 4. Hourly thermal acceptance of model 1 with current used Cd (0.6)

The lowest levels of discomfort due to overheating was observed in case 5, in which horizontal slats were applied to the window. This is explained by the adequate configuration of the shading device shape applied according the window orientation, which effectively worked as a barrier to the solar radiation, limiting solar heat gains into the room. Additionally, the greatest airflow allowed through the window also contributed to enhance the thermal comfort in the classroom. On the other hand, Case 2 resulted in the highest levels of discomfort due too cold conditions, as several horizontal shading devices was applied to the model, which limited solar gains into the room. Table 4 summarizes the thermal acceptance results for all cases tested.

Table 4. Summary of thermal acceptance conditions of cases 1 to 5

	Model 1		**Model 2**		**Model 3**		**Model 4**		**Model 5**	
	Cd = 0.34	Cd = 0.6	Cd = 0.41	Cd = 0.6	Cd = 0.57	Cd = 0.6	Cd = 0.65	Cd = 0.6	Cd = 0.65	Cd = 0.6
LOW	7%	8%	11%	12%	7%	7%	5%	5%	9%	9%
CONF	81%	83%	81%	81%	84%	84%	84%	83%	83%	83%
HIGH	12%	9%	8%	6%	9%	9%	11%	12%	7%	8%

Conclusions

The outcomes from this research contributes to a more precise prediction of the thermal performance and air quality of naturally ventilated buildings with shaded openings under tropical climate conditions providing basic guidance to designers at the conceptual design stage. In the view of the importance and lack of information of accurate characterization of the resistance the different shading devices configurations imposes to airflow, this study determines accurate discharge coefficients of five different configurations of shading devices through Computational Fluid Dynamics (CFD). Using a classroom as a generic case, corrected Cd obtained from CFD models were set to simulations on the software EnergyPlus identifying airflow levels and periods of thermal comfort under the climate conditions of São Paulo city. Models with similar characteristics but with currently used fixed Cd were also simulated for comparison.

Results indicate that the use of 0.6 as a general Cd value in simulation software is adequate for openings with shading devices that has a lower level of obstruction on the façade. However, for shading geometries with several slats and low angles, covering the opening, values as low as 0.34 were identified and corrected Cd should be considered for accurate results, as it imposes a resistance to the airflow. The greatest airflow levels were observed for the case which shading device was applied on the top of the window, which has the lowest obstructive elements amongst the models tested. The Cd value obtained in this case was similar to the usual value used (0.6). On the other hand, the model with several vertical slats angled 60° presented the lower airflow, as the shading device prevented the air from entering the room. In this case, the differences of airflow through the room was in average 15% between the models that used corrected and usual Cd.

It is important to notice that the Cd values were obtained from a CFD simulation set with a constant value for wind speed and direction. Thus, different wind conditions and shading devices configurations could be further studied in parallel with wind tunnel experimental measurements to enhance the credibility of the results from computer simulation.

Ventilation performance and end-user interaction: Comparison of natural and mechanical strategies in new-build social housing

Gráinne McGill[1*] and Tim Sharpe[1]

[1] Mackintosh Environmental Architecture Research Unit, Mackintosh School of Architecture, Glasgow School of Art, Glasgow, Scotland. Corresponding email: g.mcgill@gsa.ac.uk

Abstract: Adequate ventilation is critical to ensure effective removal of moisture, air pollutants and smells indoors. A growing body of evidence however suggests poor performance of ventilation strategies in modern housing, which raises concerns regarding the potential detrimental impact on indoor air quality. The risk of health effects resulting from exposure to indoor air pollutants is exacerbated by the reduction of natural infiltration rates brought about by improvements to the fabric performance of buildings. Whilst these improvements should help to reduce energy consumption and occupant discomfort due to draughts, there is a need to ensure ventilation does not deteriorate as a result. To ensure effective ventilation provision in modern social housing, it is important to understand and evaluate how these different strategies perform in a real-life context. This paper presents the results of a post-occupancy evaluation of three new-build social housing developments in Glasgow, ventilated by natural, mechanical extract and mechanical heat recovery methods. The study included household surveys of the three developments (responses from 63 households) and detailed monitoring of eight dwellings, to include occupant interviews, indoor environmental monitoring (during various seasons), fabric performance testing (airtightness, u-value assessment and thermography survey), energy monitoring, ventilation testing and indoor air quality measurements. The results provide interesting insights regarding how occupants engage and interact with the ventilation strategies, the performance of ventilation strategies in practice, and occupant awareness and understanding of ventilation. The findings indicate shortcomings in all evaluated ventilation methods.

Keywords: Ventilation, Social Housing, Energy-efficiency, Building Users

Introduction

Ventilation is the continual exchange of contaminated air with fresh air in a building. Ventilation is critical to dilute indoor pollutant concentrations to acceptable levels for occupant health and comfort. It is also necessary to remove moisture and smells indoors, to provide sufficient oxygen supply for building occupants and for the provision of direct and indirect comfort cooling or heating (Roaf and McGill, 2016). Ventilation is a fundamental determinant of indoor air quality in buildings. However, ventilation alone cannot ensure adequate indoor air quality (Borsboom et al., 2016).

Numerous scientific reviews have established biological plausibility for an association between ventilation rates in buildings and health outcomes (Wargocki, 2013). However the development of health-based ventilation standards have been impeded by the limited epidemiological evidence and inconsistencies regarding the way in which buildings, exposures, pollutant sources and outdoor air quality are characterised (Bischof et al., 2013). Whole house ventilation rates of at least 0.5 ach are recommended to reduce house dust mite infestation and associated allergic manifestations (Bornehag et al, 2005).

As heat loss through the building fabric decreases with improved thermal insulation, heat loss associated with ventilation (purpose provided and adventitious) becomes more substantial. The UK domestic sector has seen significant improvements in airtightness standards over the last two decades. Whilst these improvements should help reduce energy consumption and occupant discomfort due to draughts, there is a need to ensure ventilation does not deteriorate as a result.

The overall impact of improvements to fabric performance on whole house ventilation provision and indoor air quality (IAQ) in new-build UK housing has yet to be effectively determined. While emerging studies have highlighted concerns regarding the effectiveness of ventilation systems, robustness of systems in practice and end-user interactions (Howieson et al., 2013; Sullivan et al., 2013), a greater understanding of the problem is required, to increase awareness of potential performance gaps and to provide practical advice to architects and construction professionals.

To ensure sufficient ventilation provision in modern new-build social housing, it is important to understand and evaluate how various ventilation strategies perform in a real-life context. This study therefore aims to gather evidence of how passive stack, Mechanical Ventilation with Heat Recovery (MVHR) and decentralised Mechanical Extract Ventilation (dMEV) perform in a real-life social housing context, to establish an in-depth understanding of the possible causes of performance gaps and the potential implications of these. In addition, it aims to gain a deeper understanding of the importance of end-user interaction on ventilation performance.

Methodology

An initial large scale door-to-door survey was undertaken at the three sites using a short questionnaire to gain information on occupant behaviour, perception of indoor environmental quality and awareness and use of ventilation in the home. Information was gained from 63 households (response rate: 74%). Eight households were selected for detailed monitoring (Table 1), based on representativeness, availability and concerns expressed regarding environmental performance.

Detailed monitoring consisted of the following: i) Indoor environmental monitoring (Eltek IAQ data loggers), ii) Occupant interviews, iii) Airtightness testing, iv) U-value assessment (Eltek SG44 HB transmitter), v) Thermography survey (FLIR thermacam B360), vi) Sound measurements (Pulsar Real Time Analyzer), vii) Ventilation testing (Observator air volume flow meter), viii) Energy monitoring and ix) Indoor air quality measurements (Graywolf DirectSense IAQ).

Temperature, relative humidity and carbon dioxide (CO_2) levels were monitored in the main bedroom, living room and kitchen of the selected dwellings during summer and spring/winter seasons, with simultaneous measurements of external conditions. Monitoring equipment was positioned away from direct pollutant sources, in accordance with ISO: 16000:1. An occupant diary was employed to gather information on occupancy levels and activities during the measurements. Environmental data was collected at 5 minute intervals.

Results

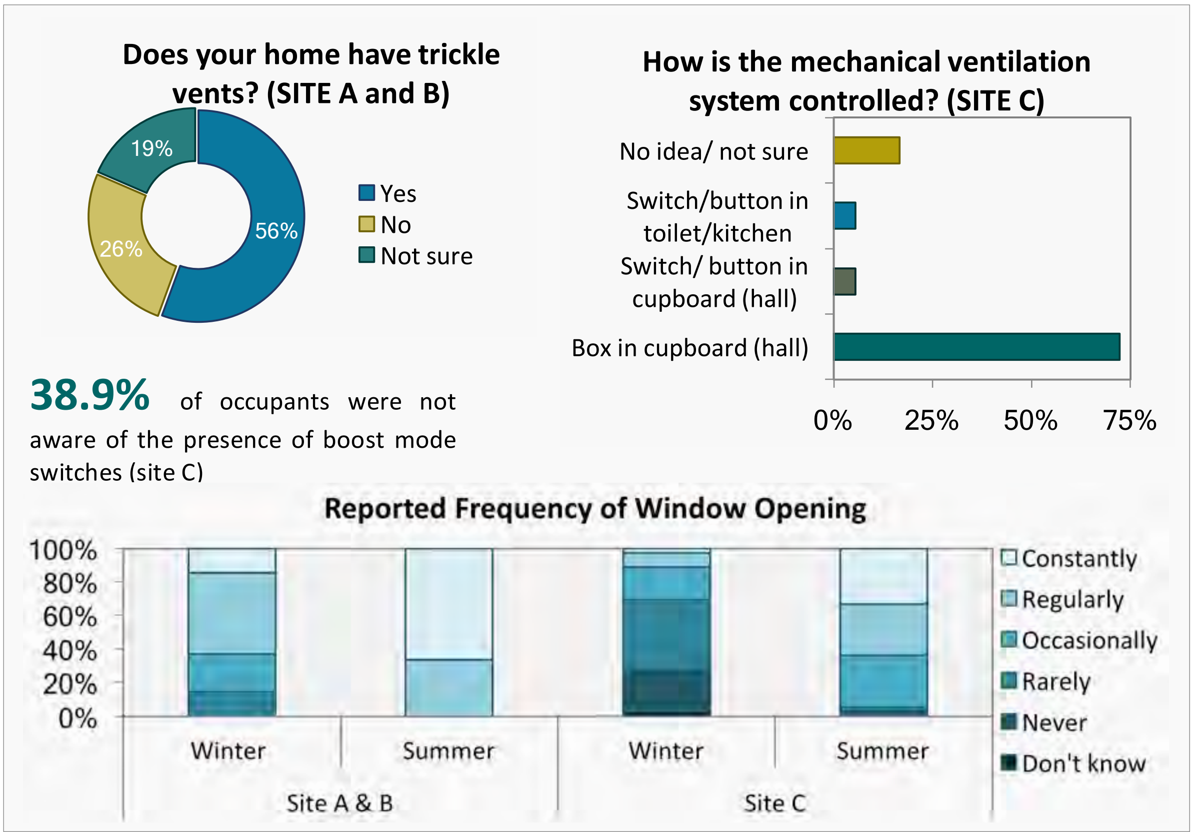

Figure 3. Household Survey results

The household survey identified a lack of occupant awareness and understanding regarding ventilation strategies in both mechanically ventilated and naturally ventilated dwellings. As illustrated in Figure 3, in homes with dMEV and passive stack ventilation (site A & B), only 56% of households were aware of the presence of trickle vents, with 26% stating that trickle vents were not present. Most households at site A&B stated that mechanical extract fans were present in their home (93%), despite many utilising passive stack ventilation (PSV). Nevertheless, 82% of households reported that they were shown how to ventilate their home during the handover process.

Similarly, at Site C (MVHR homes), although all households were aware of the presence of the ventilation system, there appeared to be a general lack of understanding regarding how the system was controlled. 39% of households were unaware of the presence of boost switches in their home to boost the ventilation rate. Of those aware of these switches, 55% stated that they were never used. Nevertheless, 89% of households at site C stated that they have never had any issues with the MVHR system. Issues that were reported included the build-up/creation of dust (6%), discolouration (3%) or faults with the ventilation system (3%).

These results correspond with the findings from detailed monitoring in the eight case study dwellings. For example, the detailed investigation found that most dMEV systems had been turned off by the building occupants at the local isolator switch (during spring and summer visits), which is likely to result in inadequate ventilation. Similarly, in homes with adjustable vents (site B); half of these were found to be in the closed position. Interviews with the building occupants revealed that dMEV systems were turned off because they were perceived to be too noisy. This was supported by the results of sound measurements in one dwelling, were levels exceeded 35 dB LAeq with the MEV system in operation.

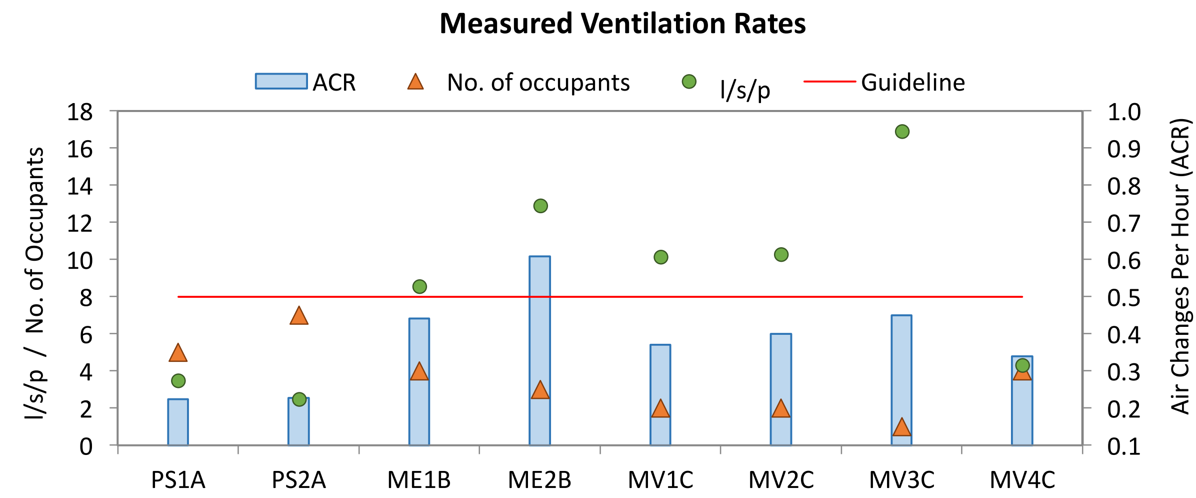

Figure 4. Measured ventilation levels

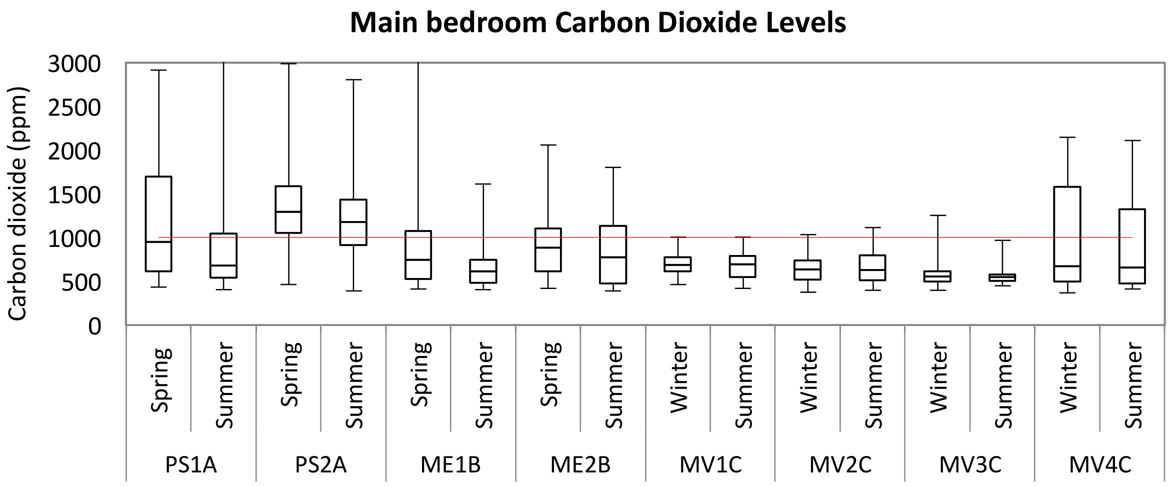

Figure 5. Bedroom carbon dioxide levels

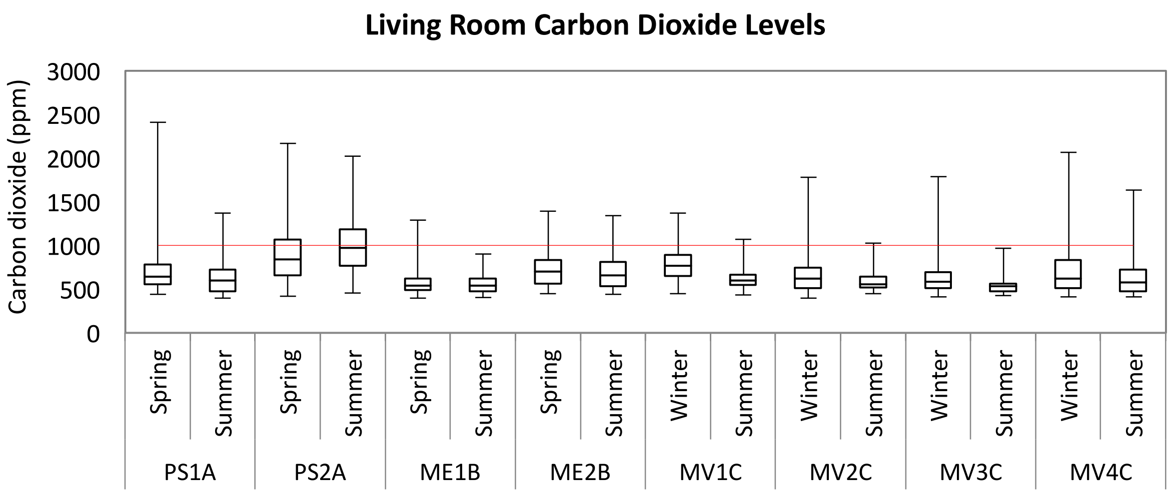

Figure 6. Living room carbon dioxide levels

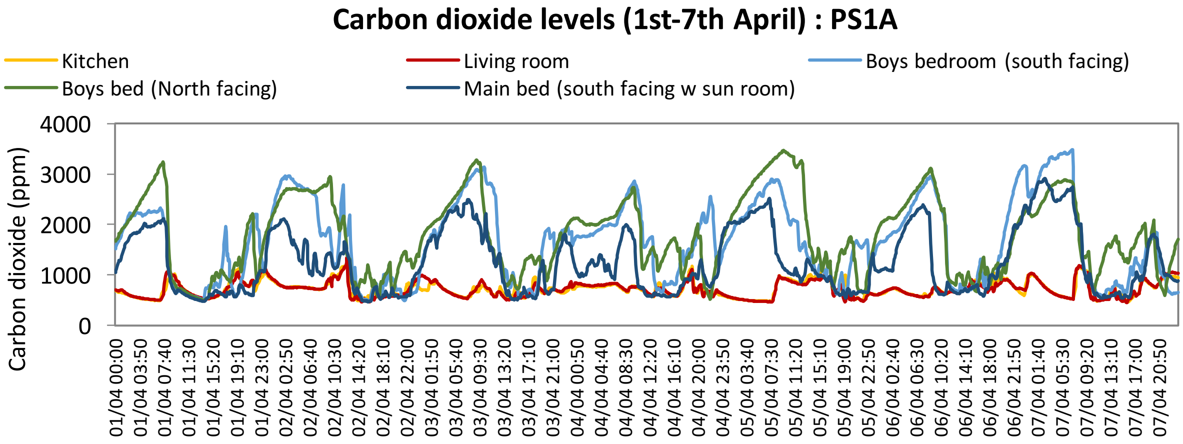

Figure 7. Carbon dioxide levels in PS1A

Physical monitoring in the case study dwellings revealed inadequate ventilation in the majority of homes. Specifically, in the four homes with MVHR systems at site C, measured flow rates (during summer and winter) did not meet design targets under normal operation. In two of these flats, a significant imbalance (>50%) was identified between supply and extract rates (favouring extract). In one home (MV2C), the detailed inspection revealed that the living room supply vent had been closed tight by the building occupants during the winter months, due to complaints of draughts. At site B, although measured extract rates in the two homes with dMEV conformed to Scottish Building Regulations, ventilation rates were likely to be inadequate given that most of these systems were deactivated by building occupants. Measurements of extract rates in two homes with PSV at site A suggest low levels of ventilation (0.22 – 0.23 ach), however these results are dependent on external conditions at the time of measurements.

Ventilation requirements in buildings are inherently linked to building occupants (Bischof et al, 2013); therefore ventilation rates are expressed with reference to the number of occupants (l/s/p), in addition to room volume (ACR). Carbon dioxide (CO_2) is often used as an indicator of ventilation levels in buildings, with levels above 1,000 ppm suggesting inadequate ventilation. Figures 4-6 present the results of physical measurements of ventilation performance in the eight case study homes. As illustrated, only one dwelling (ME2B) satisfied ventilation guidelines of both >0.5 ach and >8 l/s/p (corresponding to approximately 1,000 ppm). However, it is important to note that ventilation measurements in this home were taken when the dMEV systems were in operation, which was not representative of normal conditions. In four monitored dwellings, although ventilation rates greater than 8 l/s/p were measured, air change rates below the recommended 0.5 ach were found.

CO_2 levels peaked above 1,000 ppm in all monitored living rooms and main bedrooms during winter/spring seasons. Average CO_2 levels exceeded 1,000 ppm in the main bedroom of the two homes with passive stack ventilation (PS1A and PS2A) during spring monitoring, and in one home with passive stack ventilation during summer monitoring (PSA1). As illustrated in Figure 7, bedroom CO_2 levels were consistently high overnight in PSA1, suggesting inadequate night-time ventilation.

Discussion

This study sought to identify the degree (if any) of ventilation and environmental performance gaps, determine possible causes of these gaps and provide knowledge and insight to inform current and future developments. The household survey provided the opportunity to gain an insight into the overall performance of dwellings, while detailed monitoring helped to gain a more in-depth understanding of the possible causes of performance gaps and the potential implications of these.

The results from the household survey suggest a lack of understanding of ventilation methods in the homes. This includes confusion regarding the operation and purpose of MVHR systems (at site C), and a lack of awareness of trickle vents and confusion between passive and mechanical ventilation strategies (at site A and B). These findings are supported by the results of the detailed building surveys, which found most dMEV systems had been turned off due to complaints of noise and many adjustable trickle vents had been closed by the building occupants. Automatic humidity-sensitive trickle vents were installed in the homes with PSV, which could not be adjusted by the building occupants. Although there was no evidence of MVHR systems being deactivated in the monitored flats at site A, this is difficult to establish without prolonged metering of the ventilation system. It is important to note that whilst occupants seemed to have been briefed to refrain from interfering with the system, switches were available to deactivate the system, if they so wish to do so.

Nevertheless, households reported a high frequency of window opening, particularly during the summer season. Homes with PSV and dMEV reported a higher frequency of window opening than those with MVHR systems. However, reliance on occupants' awareness of the need for increased ventilation and subsequent response (in the form of opening windows) may be insufficient at night while occupants are asleep. This was apparent, for example, in house PS1A, where high night-time bedroom CO_2 levels evidenced poor ventilation. The findings are supported by similar studies that identified significant issues with bedroom ventilation provision (Bekö et al, 2010; McGill et al, 2015; Sharpe et al, 2014).

An important finding from the physical monitoring was the high levels of CO_2 (and low measured air change rates) in the case study dwellings. These may be attributed, in part, to occupant interference with the ventilation strategies, in the form of closing supply vents, turning off dMEV systems or closing trickle vents. The results are in agreement with those obtained by similar Building Performance Evaluation studies that identified concerns regarding ventilation noise, perceived freshness of air, perceived control, complexity and accessibility of control interfaces, and lack of understanding of ventilation in contemporary homes (Gupta and Dantsiou, 2013; Macintosh and Steemers, 2005).

Despite insufficient flow rates and lower reported window opening, bedroom CO_2 levels were generally lower in monitored homes with MVHR systems. MV4C is a notable exception; which highlights the potential risk of poor ventilation in homes dependent on MVHR. These findings however need to be envisaged in light of the poor measured airtightness (in MV2C) and lower levels of occupancy (MV2A, MV2B, MV2C) in these homes, which is likely to have significantly influenced the results. As such, the results highlight the importance of context in ventilation investigations, and support the need for detailed case studies to gain an in-depth understanding of the problem and the range of factors at play.

Nevertheless, the suggestion that modern airtight homes with MVHR systems may be better ventilated than those ventilated naturally is not surprising, given the ability of MVHR systems (in theory) to provide a continuous supply of air to a building. The findings are supported by similar studies that have demonstrated significant issues with natural ventilation strategies in contemporary housing (Dimitroulopoulou et al, 2005; Sharpe et al, 2014).

However, the application of MVHR systems in new-build dwellings represents a step change in domestic ventilation practices and as such, requires careful consideration to ensure effective design, installation, performance, maintenance and operation, particularly in a social housing context. The move towards MVHR raises further concerns, such as the longevity of systems and components, the degree of occupancy control (and resulting satisfaction), the complexity, responsiveness and transparency of systems, and the need to reduce carbon emissions (despite increasing mechanisation of buildings). These challenges need to be addressed to ensure effective, efficient, user-friendly and environmentally responsive ventilation solutions for contemporary housing.

Conclusion

The poor performance of ventilation in the majority of case study dwellings, regardless of the ventilation strategy employed, highlights the fundamental need for improvements to ventilation provision in contemporary housing, particularly those designed to high levels of airtightness. Issues with end-user engagement and interaction in homes with dMEV and MVHR suggest significant advancements are required to ensure these systems are designed and installed in a way that is user-friendly, transparent, engaging and even captivating to building users. It is hoped that the findings of this study might help to shed light on potential causes of ventilation performance gaps in contemporary housing, whilst highlighting the need for greater consideration of the end user in ventilation design.

Assessment of Natural Ventilation for Air Renewal and Thermal Comfort in Offices in Mexico City

Elisur Mogollon[1], Gloria Castorena[1], Victor Fuentes[1] and Pablo La Roche[2]

[1] Postgraduate in Bioclimatic Design, Division of Science and Arts for Design, Universidad Autónoma Metropolitana, Mexico City, Mexico, email: elisurmogollon@gmail.com; gmce@correo.azc.uam.mx; ffva@correo.azc.uam.mx;
[2] Faculty of Architecture, Cal Poly Pomona University, Los Angeles, USA, email: pmlaroche@cpp.edu

Abstract: In order to achieve thermal comfort and the renovation of air in buildings, natural ventilation has been relegated by mechanical and conditioning systems. These are commonly designed without taking into account the climatic conditions or the needs of the user and they are responsible of a large percentage of respiratory diseases. For the present study, a nucleus of offices located in the Metropolitan Autonomous University, in Mexico City, was analysed. User surveys were applied and measurements of temperature, humidity and wind speed during the pre-occupation period and the warm period were made. The measurements showed an increase of the temperature in the working days and a correlation with the answers of the occupants was observed. On the other hand the relative humidity stays in acceptable ranges of comfort; between 55% and 40%, due to microclimatic conditions. Currently, the wind does not influence the users' thermal sensation. The measurements show areas with greater air movement, generally in the perimeter of each zone, probably originated by the interior distribution and the occupation. The positive and negative effects of ventilation should be evaluated, which will focus on dissipating heat gains due to the occupation and operation of the building.

Keywords: Natural ventilation, thermal comfort, heat gains, air movement, air quality.

Introduction

Currently, the use of natural ventilation in a building has been limited by the use of conditioning systems and mechanical ventilation, which are designed without taking into account local climatic conditions and in many cases without regard to occupation and operation of the building. According to OMS, 75% of chronic diseases of the human respiratory system are mainly due to the inadequate conditions of their living spaces (García et al, 2005). This coincides with data from real estate specialists, which show that at least 30% of the employees working in the nearly 200,000 public and private offices in Mexico, suffer from diseases associated with poor design of ventilation in buildings (El Universal, 2013).

With regard to energy consumption, the energy used for air conditioning and mechanical ventilation can represent up to 50% of energy consumption, depending in part on regional climatic condition (CONUEE, 2015). The energy consumption by using air conditioning and mechanical ventilation is very high and brings with it great economic costs and serious environmental and health consequences.

An adequate design of natural ventilation will benefit the health of the occupants, providing an adequate indoor environmental quality. Taking into account bioclimatic strategies in the development of a project will reduce dependence on artificial ventilation systems, contributing to the comfort conditions in the environment, as well as the reduction in the use of energies that propitiate the global warming and the deterioration of the environment.

Analysis of offices of Direction CyAD

As a case study, a nucleus of offices located at the Universidad Autónoma Metropolitana, in Mexico City was analysed (19°30’11” N / 99°11’13” W, and 2,240 m above sea level). The climatic condition is “semifrío seco”, based on the bioclimatic grouping of Fuentes and Figueroa (1988). The weather is: BS1kw(w)(i’)g according to the Köppen García classification (García, 1973), which is described as dry with little thermal oscillation and without presence of heat. The zone have ranges of average outdoor air temperature between 13.5°C and 19 °C, with a maximum of 26.7°C and a minimum of 4.7°C., with a total annual precipitation of 592 mm and a relative humidity of 50% with an ± 6 oscillation. The dominant winds have a South-West direction with prevailing winds in the same direction. Calms account for 24%.

The offices are located on the ground floor of University, Building H (See Figure 1). The access is located in the central courtyard of this building. The construction is made of of block, reinforced concrete and aluminium glazing with clear glass of 6 mm. The internal divisions are of gypsum board with vinilyc painting, aluminium glazing with clear crystal of 6 mm. And louver in the enclosures.

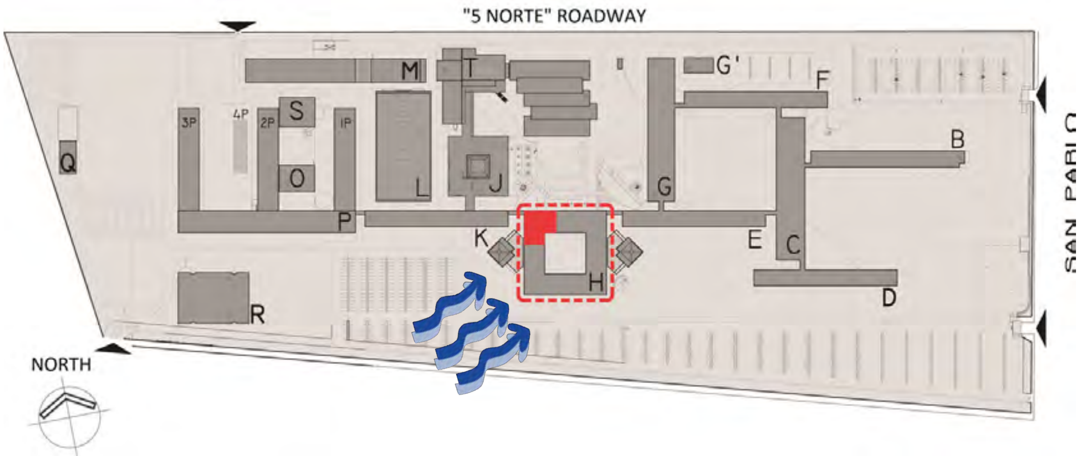

Figure 1. Location of Direction CyAD offices. UAM-Azcapotzalco

The offices have a constructed area of 334 m2 and a height of 2.60 m / 3.00. They consist of a series of private cubicles and group spaces, the cubicles communicate through a common area, where there are open workstations. The offices have natural ventilation, supported by mechanical extractors in some of their spaces. The window area represents almost a third of the total building area, however the area of operable windows is barely 8 m2, which is 8% of the surface of openings and 2% of the total construction surface. It is important to note that the openings are protected from direct solar radiation by an exterior eave on all its facades. The architectural distribution and the location of the measurement points are shown in figure 2.

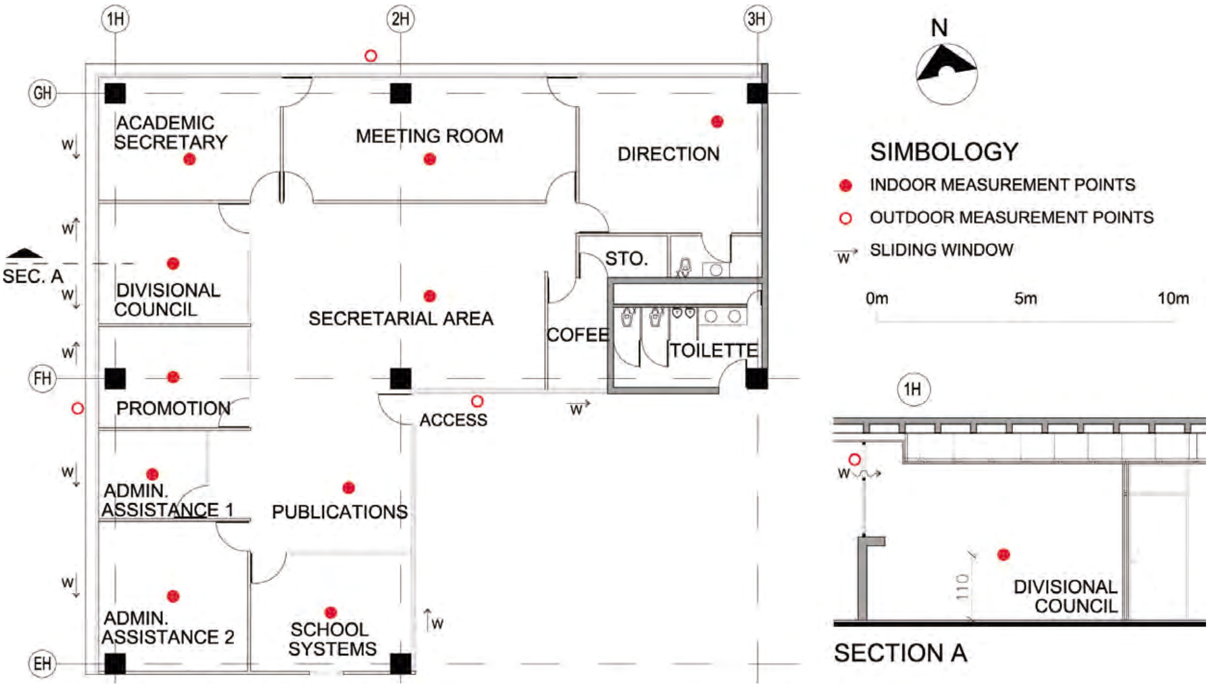

Figure 2. Architectural plan, offices. UAM-Azcapotzalco

The classification of areas was done in spaces with occupation and without occupation. The offices are occupied by 20 users of full time, the majority are in a range of age between 35 and 64 years; they are dedicated to administrative activities, which develop seated. The metabolic rate is 1.0, with a CLO factor of 0.89, which corresponds to overalls, long-sleeve shirt, t-shirt, according to the parameters of ASHRAE 55-2013. The classification of areas is shown in table 1.

Table 1. Classification of areas. Offices of CyAD

Private areas	Group areas	Non-occupancy spaces
Direction	Secretarial area	Coffee area
Academic secretary	Meeting room	Storage
Divisional council	School systems	
Income and promotion	Administrative assistance 2	
Administrative assistance 1		

Thermal conditions

In order to determine the thermal conditions of the space, measurements of air temperature, inside and outside, relative humidity and air velocity were carried out in accordance with the requirements of ASHRAE 55-2013, this during two different periods: pre-occupation and warm period. Graphs from an average of 24 hours were plotted. They also include the comfort zone defined by the Neutral Temperature (Tn), with a thermal amplitude of ± 2 K according to the linear equation of Auliciems (Auliciems and Szokolay, 1997) for adaptive comfort:

$$Tn = 17.6 + 0.31\, Tmed$$

Figure 3 shows the daily average of the measurements made in the month of February, prior to the occupation. It is perceived that the interior temperature conditions are slightly cold throughout the day, with little thermal oscillation (3 K), and very different from the outside, where there is an oscillation of 9 K, with temperatures ranging from 17 At 26 ° C. This can be attributed to that the windows do not have direct incidence of the sun, so the space is not affected by variations of the conditions of the outside environment.

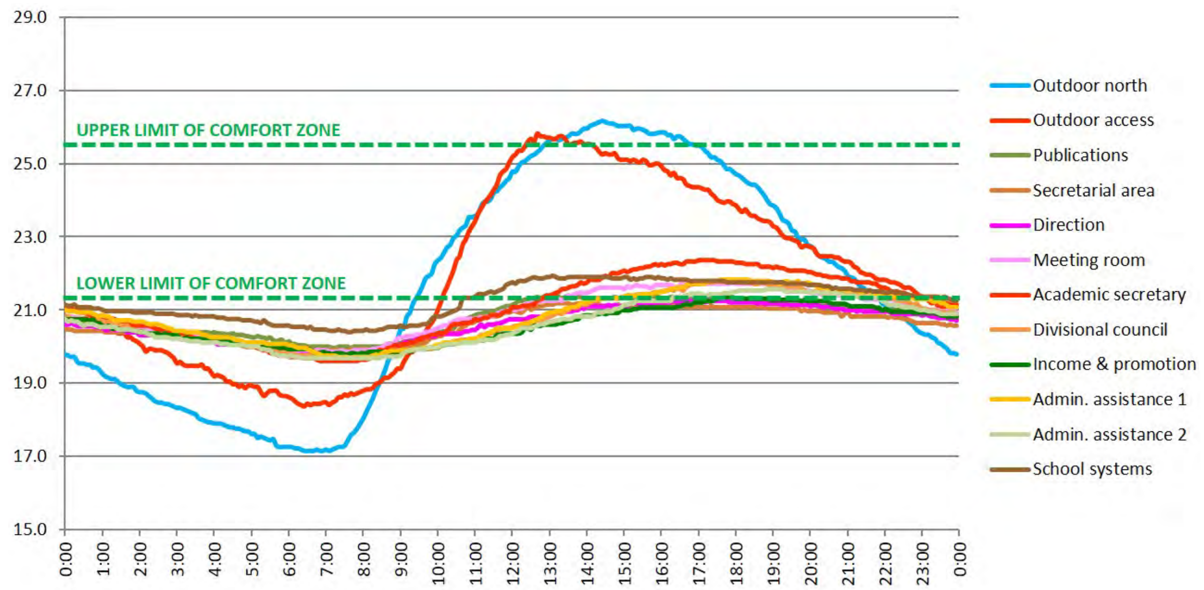

Figure 3. Average temperature in 24 hours. Pre-occupancy period

Figure 4 shows the average daily temperature in the warm period, which occurs in May. In contrast to the unoccupied period, the graph shows how the occupation and operation of the space has a significant influence on the interior temperature, since there is an increase in temperature in the working days (Monday to Friday) between 10:00 AM and 7: 00 PM.

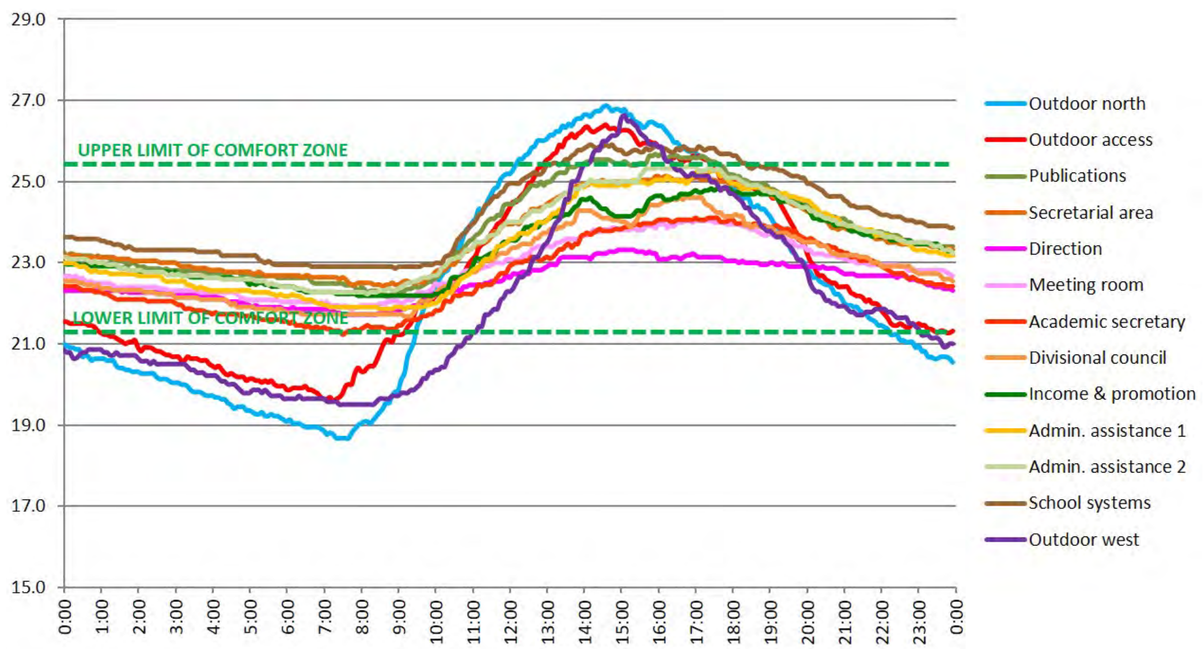

Figure 4. Average temperature in 24 hours. Warm period

During the warm period, the outside temperature is maintained between 19 °C and 27 ° C and the indoor temperatures range from 21.5 ° C to 26 ° C. Half of the spaces are located near the upper limit of the comfort zone. Variations in temperature are due to several factors: number of users per space, working hours and in some cases the level of control that occupants have to achieve comfort in their work areas, such as operable windows, mechanical extractors and individual fans.

Relative Humidity Analysis

In order to know the levels of humidity saturation in the space and its affectation in the occupants, a daily average of the relative humidity of the warm period was made (see Figure 5). With a maximum HR of 65% at 7:00 AM on the outside and a minimum of 35% at 3:00 PM. The indoor relative humidity is stable at night, with a maximum of 53% at 10:00 AM in the Direction office and a minimum of 40% in the secretarial area at 3:00 PM. Although there are significant variations of relative humidity, this is always in acceptable ranges of comfort; between 55 and 40%, according to the hydric comfort parameter ± 20% from 50% RH (Fuentes, 2004), even though the site is classified as "Semifrio-Seco" according to the bioclimatic grouping of Fuentes and Figueroa (1988). Therefore it is concluded that microclimatic conditions prevail in the University environment, due to the amount of green areas adjacent to the offices.

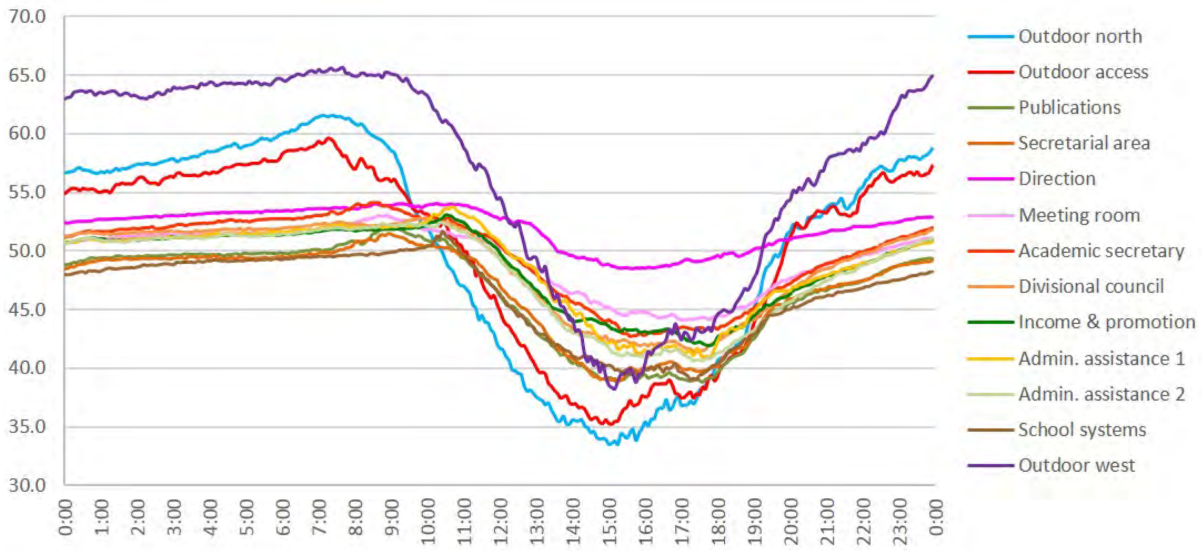

Figure 5. Average relative humidity in 24 hours. Warm period

Wind analysis

Wind measurements during the warm period were made, with hot wire anemometer. Average velocities of 0.05 m/s were recorded in open spaces with direct incidence of external wind, and velocities of 0.01 m/s in cubicles and closed areas. It follows, therefore, that currently the speed of the wind to the interior does not influence the thermal sensation of the users, reason why adjustments to take advantage of the natural ventilation must be made. The measurements also showed that there are areas with greater air movement, close to the limits of the space, but not less than 0.30 m away from the walls or obstructions

Since vegetation and architecture play an important role, it was sought to establish the parameters of wind behaviour outside the offices. Wind measurements were performed around the building every 3 minutes during the one hour interval to record wind behaviour patterns. With this information the wind velocities were determined, with a speed air average of 1 m/s and a maximum of 1.5 m/s, without exceeding 2 m/s, with a west direction in the north facade, and South-West direction in the west facade, and absence of wind on the south east facade. These data coincide with the collected climatic information.

Hygrothermal comfort surveys

In order to correlate the results of the comfort model with the indoor temperature conditions, user surveys were applied during the hot period, to a total of 18 occupants, according to ASHRAE 55-2013. Although this sample is not representative to validate similar studies, it is for the present case, as established by the reference standard. Perceptions of temperature and humidity of the users are shown in Figures 6-7, which coincide with the thermal conditions obtained in the measurements.

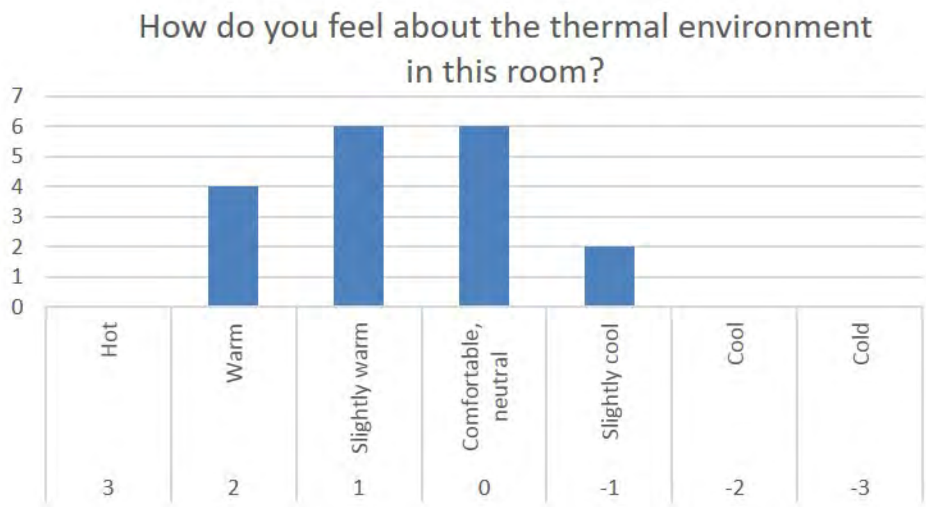

Figure 6. Temperature perception of occupants

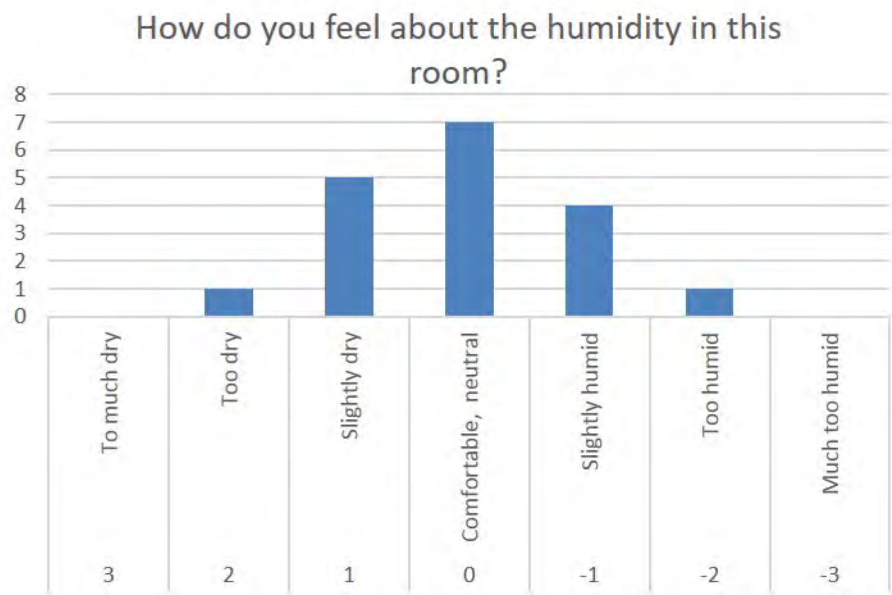

Figure 7. Humidity perception of occupants

Perception of ventilation is an important factor of the study, 50% of the respondents perceive a light ventilation inside the spaces, however, 44% perceive no ventilation and only 6% indicates a medium level of ventilation. The trend is confirmed by occupant ventilation preferences, as 81% would prefer higher levels of ventilation and only 6% indicate that they would like less ventilation, while 13% are satisfied with the supplied air.

Discussion

Based on the thermal analysis and the current conditions we can say that thermal comfort is a problem in half the spaces, and the rest are in comfortable conditions: Direction, Academic Secretary, Meeting room, Divisional council and Income and promotion. The rest of the zones are in thermal conditions near the upper limit of comfort. The most problematic spaces are located on the south-west side, which indicates that it is possible to take advantage of the external wind conditions to promote heat loss through ventilation. A simple calculation determines the potential of ventilation. According to the formula of R. Aynsley (cited by Fuentes, 2004), it is possible to estimate the speed of the wind necessary to restore the thermal comfort in the spaces. Entering the value of the maximum comfort limit of the case study:

$$v = 0.15\ [T - 25.4 + 0.56\left(\frac{HR - 60}{10}\right)]$$

This indicates an increase in the air velocity with which the interior comfort levels would be restored in the 5 areas with comfort problems, as shown in Table 2:

Table 2. Wind speed required

Space	Max. indoor temp.	Required air speed (m/s)
School systems	25.9	0.24
Publications	25.6	0.19
Administrative assistance 2	25.4	0.15
Administrative assistance 1	25.0	0.09
Secretarial area	25.1	0.12

The rest of the spaces, are in acceptable levels of comfort, reason why the requirements of ventilation are limited only to the air renovation. This shows that with some adjustments to the ventilation openings the requirements could be met and adequate levels of comfort can be achieved during the warm season.

Conclusions

There is a correlation between the results of the measurements and the surveys applied to the users. According to the analysis of the temperature, there are comfort conditions in the middle of the spaces during the warm season, however, there are areas that require adjustments to improve thermal conditions, such as School Systems, Publications and Administrative assistance 2, which are the areas with the highest occupancy.

Although a third of users find their work environment comfortable, and half of them perceive a light ventilation feel, most of them would want a cooler, more ventilated environment, and all spaces must increase ventilation levels to improve indoor environmental quality. This indicates that, although the thermal factor influences the environment conditions, air quality and quantity are important.

Although the wind conditions are minimal, the measurements show areas with greater air movement, generally in the perimeter of each zone, probably by small turbulences originated by the interior distribution and occupation. More detailed measurements are recommended to establish patterns of wind behaviour in each of the zones. It is established that the velocity of the air and its distribution within a space is not uniform, however, it is convenient to consider an average internal air velocity that helps determine the ventilation rates in the space.

Because there is no direct solar gain on any of the facades, the use of ventilation will be mainly used to dissipate heat gains, due to the metabolic heat of the occupants and the radiation of electronic equipment.

For comfort requirements, the effect that the wind has on the space must be evaluated both positively and negatively. In the warm season, small entrances are advised, directing the flow towards the zones of activity and great exits to propitiate an adequate air flow, as well as a free distribution without elements that hinder the inner flow and block their flow during the winter.

Due to the size of the sample studied, these conclusions are unique to this specific case, and cannot be validated for similar projects, so that similar cases should analyze their specific climatic conditions, space design and occupation.

The Pacific Breezes: Estimation of the overheating risk and the natural ventilation potential for buildings in cities of the Chilean Pacific Coast

Massimo Palme[1], Claudio Carrasco[1] and Miguel Angel Gálvez[3]

[1] School of Architecture, Catholic University of the North, Antofagasta, Chile

Abstract: Global Warming and Urban Heat Island are phenomena that are worsening the building energy performance, increasing the cooling demand in summer time of any kind of buildings. Moreover, accomplishing the most restrictive laws on energy savings (principally developed to avoid thermal losses during the cold season), is leading in many countries to a substantial overheating of the spaces in summer and in some cases even in winter. One of the best strategies to avoid overheating is the use of natural ventilation, especially where breezes are almost constant during the day and year. This is the case of the long Chilean Pacific Coast, where many of the most important cities of the country are placed. This paper compares a steady-state evaluation method and dynamical simulations to estimate the cooling demand of family houses and the reduction of this demand due to the use of natural ventilation (wind driven) in eight cities. Results show that the more than the 30% of the cooling demand could be eliminated by natural ventilation systems. The inclusion of this kind of evaluation in the buildings energy certification system could benefit the entire country in terms of energy demand and greenhouse gases emissions reduction.

Keywords: Cross-ventilation, overheating, passive cooling, thermal codes, Chile

Introduction

During the last 50 years, the concept of “passive architecture” and the need of reducing energy consumption and greenhouse gases emissions have been constantly related. However, in some cases good intentions load to wrong results. It is the case, for example, of many bioclimatic buildings that are very sensitive to changes in the environment like urban heat island or global warming (Toledo, 2016; Palme, 2015; Palme et al., 2016a; Jenkins et al., 2009). Most of the design rules applied today, can lead to a wrong building performance in the near future, basically due to excess of heat in summer. To avoid the overheating sensation of users without increasing the energy consumption, especially of electricity, is a challenge for the architecture of the XXI Century. In countries like Chile, the challenge is even more important, because of the change in the purchasing power of the middle class family. Today, residential buildings are normally naturally ventilated and have no cooling systems. However, this situation can change drastically in the next years. Residential buildings constitute more than the 70% of the total built environment and the impact of the sector on the total energy consumption could be very high.

Methodology

In this paper a steady-state assessment (based on the ISO 13790) is done in order to establish the overheating risk and the natural cross ventilation potential to evacuate the heat in excess during the summer season, considering 90 days (from January to March). A set of simulations was performed with the natural ventilation option available in Design Builder, in order to control the results capability. Design Builder was selected because of the facility in the result comparison with and without natural ventilation (Tronchin 2008). A family house is evaluated in different conditions of orientation facing the wind (90º or 45º) and of internal distribution (well connected or poorly connected). Emplacements studied are the Chilean cities (from North to South) of Arica, Iquique, Antofagasta, La Serena, Valparaíso, Concepción, Valdivia and Puerto Montt. All these cities are coastal cities in a region of the world characterized by constant and intense breezes from the sea to the land (land-sea breeze is sometimes present but not constantly, due to the effect of the Andean Cordillera on the air flows). In this study, the wind is supposed always coming from S-W, without modifications due to the urban environment.

Overheating risk calculation

Overheating risk is calculated by using a method based on the EN ISO 13790 (2008), which considers average daily temperatures and a correction to take into account the heat accumulation in the thermal mass. To estimate the overheating, many factors are considered. The following equations resume the method. First term to be considered is:

$$SGO = R \times S \times \alpha \times R_{es} \times U \tag{1}$$

Where:

SGO is the solar gain through the opaque envelope elements (J)
R is the incoming solar radiation (J/m^2)
S is the surface of the opaque element (m^2)
α is the solar absorption of the surface
R_es is the external surface thermal resistance (m^{2}K/W)
U is the transmittance of the element (W/Km^2)

The second term is:

$$SGW = R \times S \times f_f \times f_{sg} \times f_{mp} \times f_a \tag{2}$$

Where:

SGW is the solar gain through the windows (J)
R is the incoming solar radiation (J/m^2)
S is the surface of the element (m^2)
f_f is the framework coefficient of the window
f_{sg} is the solar factor of the glass
f_{mp} is the factor of mobile protection of the window
f_a is the accessibility factor due to external shadows

The third term to be considered is:

$$IG = \sum P \times S \times t \tag{3}$$

Where:
IG is the internal heat gain (J)
P is the heat generated by each appliance and by people (W)
S is the floor surface of the zone (m^2)
t is the time of functioning or occupation (s)

The total gain is expressed by:

$$TG = IG + \sum SGO + \sum SGW \tag{4}$$

Part of this heat is evacuated by thermal transmission trough the envelope and the other part represents the overheating OH:

$$OH = TG - \ (T - T_A) \times H_t \times \eta \tag{5}$$

Where
T_A is the daily average temperature (ºC)
T is the internal temperature (set as adaptive comfort temperature)
H_t is the thermal loss (J/ºC) by transmission trough the envelope
η is the efficiency of the heat loss and depends on the thermal mass

Adaptive comfort concept refers to the maximum temperature that people used to live in free-running buildings will accept as comfortable. This temperature depends on the external temperature and has been expressed by different experimental formulas (De Dear and Brager, 1998 and 2002). In this paper the expression used is:

$$T = \max(0.35\, T_A + 17.8\, ; 26) \tag{6}$$

Meteorological data used in calculation are obtained by ASHRAE (temperatures) and by using epw files (solar radiation) produced by Meteonorm tool and processed by using TRNSYS 17 in order to obtain the radiation on the vertical surfaces. Table 1 resumes the data (average temperatures and total radiation during the summer season (January-March).

Table 1. Radiation and temperature for the considered cities

	H(MJ/m^2)	N(MJ/m^2)	S(MJ/m^2)	E(MJ/m^2)	W(MJ/m^2)	T_A (°C)	T 8-20h
Arica	2040	740	704	1210	1110	22.6	24.9
Iquique	2125	775	675	1206	1180	21.9	23.4
Antofagasta	2160	817	625	1240	1170	20.1	22.8

Valparaíso	1670	835	599	1030	958	21.5	25.2
Concepción	1877	980	591	1134	1128	16.2	19.0
Valdivia	1650	950	582	1021	1017	15.2	18.3
P. Montt	1547	931	545	970	960	13.7	15.7

Natural ventilation assessment

Natural ventilation potential is estimated by using a simplified method, also following EN ISO 13790. To evaluate the natural ventilation capacity to evacuate heat, the following equation can be used:

$$NVH = (T - T_v)\times(H_v)\times\eta \tag{7}$$

Where:

NVH is the heat removed by natural ventilation (J)
T_v is the air temperature (daily average or 8-20 average depending on the case) (ºC)
H_v is the thermal loss (J/ºC) by ventilation
η is the efficiency of the heat loss

The thermal loss by ventilation is expressed as:

$$H_v = t\times\delta\times sh\times q \tag{8}$$

Where:
t is the period (s)
δ is the density of the air (kg/m^3)
sh is the specific heat of the air (J/kgK)
q is the flow (m^3/s)

The airflow has to be assessed by analyzing the geometric characters of the house and the windows typologies and depends on few parameters: two discharge coefficients cd,i and cd,o (inlet and outlet of the air), two pressure coefficients cp,I and cp,o (on the façades where the windows are placed) and one internal coefficient ci (depending on the space distribution and connection).

The final formula is:

$$q = v\times\sqrt{\frac{|c_{p,i}-c_{p,o}|}{\frac{1}{c_{d,i}^2\times s_i^2}+\frac{1}{c_i^2\times s_d^2}+\frac{1}{c_{d,o}^2\times s_o^2}}} \tag{9}$$

Where s are the surface of inlet, distribution and outlet respectively.

Final heat to be removed (FRH) can be expressed as:

$$\text{FRH=OH-NVH} \tag{10}$$

By comparing the overheating OH and the final heat to be removed FRH the effectiveness of the natural cross-ventilation can be obtained.

Two house orientations respect the wind and two internal distributions are tested in this work. Figure 1 shows the well connected and the poorly connected distribution of the houses. Table 2 shows the house and windows dimensions. The house has only two windows, on each of the main façades. Pressure coefficients depend on the relationship height/width and length/width of the house. Table 3 resumes the coefficients used and the air flows calculations for the two considered orientations. Air speed used is 1 m/s. Details for coefficient calculation are described in many contributions, like the work of Heiselberg and Sandberg (2016).

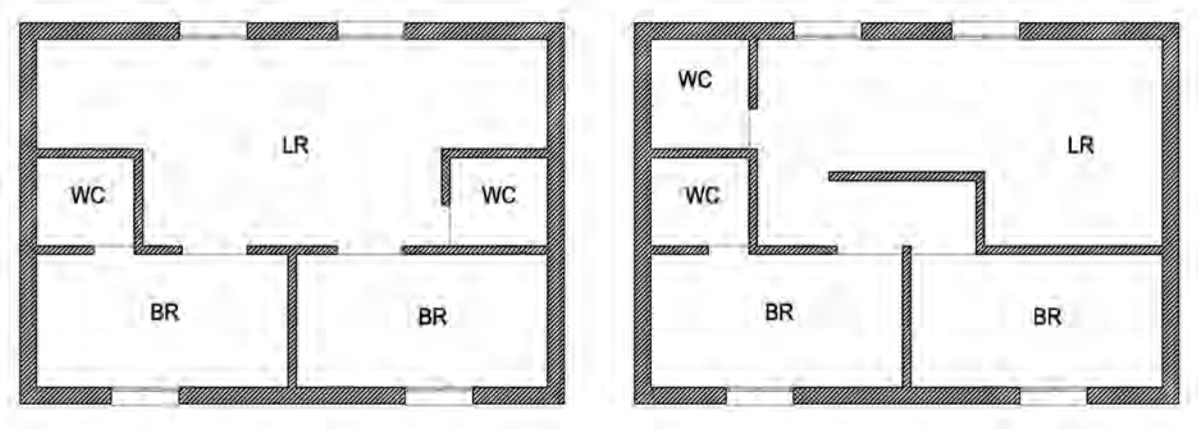

Figure 1. Well connected and poorly connected house

	Cpi	Cpo	Cdi	Cdo	Ci (wc)	Q (wc)	Ci (pc)	Q (pc)
House 45°	0.10	-0.35	0.70	1.00	0.80	0.94 m^3/s	0.30	0.39 m^3/s
House 90°	0.70	-0.20	0.70	1.00	0.80	1.3 m^3/s	0.30	0.56 m^3/s

Dynamical simulations

Simulations are conducted by using Design Builder tool with and without the "natural ventilation" application available in the tool. The natural ventilation module automatically uses the external air to reduce the overheating when possible and turn on the air-conditioning when necessary (mixed mode). The air flow is calculated by the AIRNET module in Energy Plus. For detailed description, see for example the work of Gu (2007) and the manual of the software. Figure 2 shows the network model. Table 4 shows the transmittance values used in simulation and steady-state evaluation. These values come from the Chilean thermal standard (MINVU, 2008) of the Dwelling Ministry (maximum transmittances per climate zone). Internal gains were set to 25 W/m^2, occupancy was considered of 24 hours.

Table 4. Walls, roofs and windows transmittances (W/m^{2}K)

	Arica	Iquique	Antofagasta	La Serena	Valparaíso	Concepción	Valdivia	Puerto Montt
Wall	4	4	4	4	3	1,7	1,6	1,1

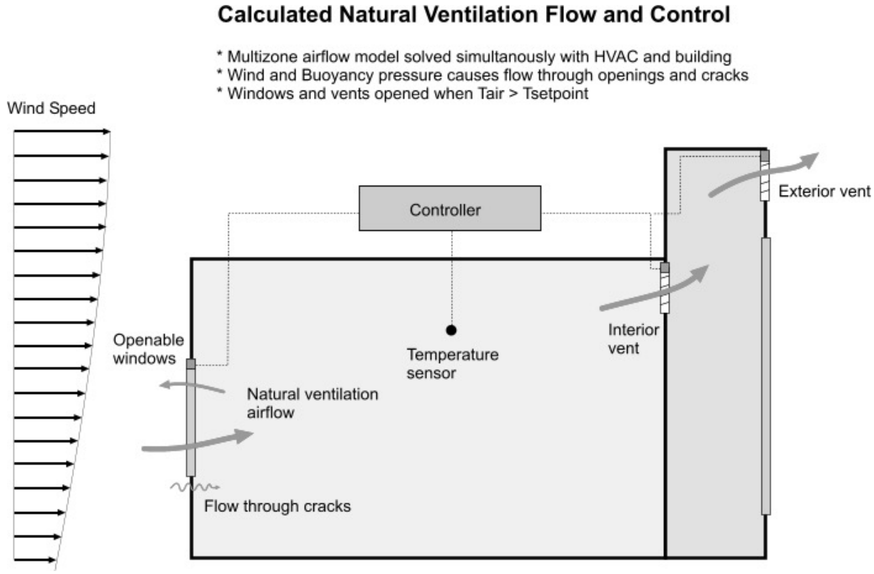

Figure 2. Natural ventilation model (picture from www.designbuilder.co.uk)

Results and discussion

Table 5 resumes the results of the steady state evaluation and dynamical simulation, considering natural ventilation and without considering it. Steady-state evaluation shows energy savings in the range 30-90% depending on the location, orientation and internal distribution. This result is according to previous studies (Palme et al. 2016b). Dynamical simulations results is also according to the steady state evaluation in terms of energy saving. Cooling demand calculated by dynamical simulation is in general lower than the estimated overheating, probably because of simplifications in the steady-state model, especially regarding the calculation of the solar gains. It could surprise that the cooling demand estimated by steady-state analysis is higher in the southern cities like Valdivia and Puerto Montt than in central cities like La Serena, but this fact is explained by the different transmittance values used: southern cities have to use more insulated walls and roofs to accomplish the norm. Besides the difference in the simulated or simply evaluated energy demand, the resulting energy savings obtained by using natural ventilation are very close to the estimations in most of the analysed cities. This general result allows this methodology as a very simple tool that can be incorporate in the actual thermal code of the Housing Ministry, which today is not considering a numerical evaluation of the cooling demand (Palme, 2014; Palme and Vasquez, 2015). The incorporation of energy labelling in terms of natural ventilation performance in the National Energy Certification System will probably avoid the generation of an unnecessary cooling systems demand of the Chilean market.

Conclusion and future work

In this work the wind-driven ventilation has been assessed as a passive strategy to reduce overheating in small houses in Chile. Future work should consider convective ventilation (by temperature differences) and more building typologies. Other interesting issue to be investigated is the influence of the urban heat island (UHI) on the cooling needs, and the modifications in the effectiveness of the natural ventilation due to the same UHI. It seems that increased urban temperatures should generate a forcing effect on the air speed, because of the increased difference between Sea and land temperatures (Lebassi 2011). Other works estimates a global decrease in the natural ventilation potential under UHI effect (Palme et al. in press). Climate change is other topic to be considered in assessing the changes in the ventilation patterns of coastal environments.

Computational Investigation of Natural Ventilation in an Educational Building in Madurai, Tamilnadu

S Subhashini[1], K Thirumaran[2]

[1] Department of Architecture, Thiagarajar College of Engineering, Madurai, India, email-ssarch@tce.edu;
[2] Department of Architecture, National Institute of Technology, Trichy, India, email-ktm@nitt.edu;

Abstract: Natural ventilation in educational buildings plays a vital role in energy conservation, thermal comfort, indoor air quality and reduction of carbon emission. This paper investigates the natural ventilation performance of a School of Architecture building located in the warm humid climatic zone of India. The study involves three phases, an evaluation of occupant's perception on overall comfort (summer, winter and monsoon) using Building Use Studies workplace survey, field measurements of outdoor and indoor weather conditions like temperature, air velocity and relative humidity and Computational Fluid Dynamics (CFD)- based simulations for the whole building. The numerical simulation on the discretized domain is carried out using ANSYS Fluent. The boundary conditions necessary for the CFD study were obtained from the experimental data measurements. The lowest air velocity recorded in the summer month has been considered for the simulation to understand the influence of architectural design of the building on natural ventilation. As a result, the unique characteristics of air flows within classrooms and studios were determined, and ventilation processes in various situations have been analysed, discussed and compared with the BUS survey results to validate each other.

Keywords: Natural ventilation, air flow, Computational Fluid Dynamics (CFD); occupant comfort.

Introduction

Natural ventilation may be defined as ventilation provided by thermal, wind or diffusion effects through doors, windows, or other intentional openings in the building as opposed to mechanical ventilation that is ventilation provided by mechanically powered equipment such as motor-driven fans and blowers. These natural ventilation systems may reduce both installation and operating costs compared to mechanical ventilation systems while maintaining ventilation rates that are consistent with acceptable indoor air quality (Emmerich et al, 2001). Occupants of naturally ventilated buildings are often more tolerant of fluctuations in the indoor climate (Brager, 2001). They tend to accept a wider range of temperature and humidity levels.

Consequently, in the recent decades, many researchers have investigated the airflow patterns, the temperature and contaminant distributions, and thermal stratification comfort as well as the effects of thermal buoyancy and wind force for naturally ventilated rooms or buildings (Nielsen 2002, Ramponi et.al, 2011, Yang et.al. 2014, Calautit et.al, 2015). However, the aforementioned most of researches and experiences of natural ventilation were focusing on the residential and office buildings but very few researches have been carried out for educational buildings in hot climates (Wang et.al 2014, Beltrán et.al. 2015). Classroom environment and thermal comfort has an important role in the teaching and learning as it could be engaging students in activities that promote their performances, such as understanding of concepts, abilities of problem solving, attitudes towards learning, and etc. With the technology of CFD wind environment simulation, architects are able to better forecast and more intuitively describe the building wind environment in a design scheme, and conduct an analysis based on relevant building technologies and simulation results, with which they can make comparisons among various options and improve the design scheme (Guo et.al, 2015). The study involves three phases, an evaluation of occupant's perception on overall comfort (summer, winter and monsoon) using Building Use Studies workplace survey, field measurements of outdoor and indoor weather conditions like temperature, air velocity and relative humidity and Computational Fluid Dynamics (CFD)-based simulations for the whole building. A post occupancy evaluation of the building was also carried out using BUS methodology (Leaman and Bordass 2001) to understand the occupant's perception on thermal performance, lighting and indoor air quality. In this case the thermal comfort results are derived from the mean scores and open ended comments on users' experience and assessment of temperature, air, lighting and overall comfort from the BUS survey data rather than the PMV (Predicted mean vote) model (Fanger 1970) or adaptation model (De dear,1991) . The survey results showed thermal discomfort during summer. Thus field measurements of the indoor and outdoor weather conditions were recorded for the month of March 2016 using hobo data loggers and Watchdog 2700 weather station. Taking the lowest air velocity of the outdoor wind environment from the experimental data the CFD based simulations were carried out to explore the effect of natural ventilation in the building design when wind speed is very low. The main purpose of this study is to understand the influence of building design on natural ventilation and thermal comfort. The numerical simulation results of the airflow properties were very helpful to form a digitized database system and allow us to understand the interaction between the building structures and the urban wind environment.

Building description

The architecture department building is located inside the campus of Thiagarajar College of Engineering; Madurai .It is an isolated two storey building consisting of design studios, lecture halls, an audio visual hall, a library and staff rooms surrounding two courtyard spaces. The building is oriented towards east west axis (Figure 1). It is a naturally ventilated building with fans for mechanical ventilation. Temperatures during summer, in the months of March to June reach a maximum of 40°C and a minimum of 26.3°C**.** Winter temperatures range between 29.6°C and 18°C between the months of December and February (Subhashini 2015). The relative humidity typically ranges from 37% to 96% over the course of the year. Over the course of the year typical wind speeds vary from 0 m/s to 10 m/s. The highest average wind speed of 6 m/s occurs around July and the lowest average wind speed of 3 m/s occurs around March. There are no hills in the region of the Madurai Corporation limit. Therefore, the existing topography of this city experiences horizontally homogeneous wind flow and more or less steady-state meteorological conditions.

Figure 1. Top view of Architecture department, TCE, Madurai

Post occupancy evaluation outcomes

The occupant survey used was the Building Use Studies Survey (BUS) Workplace Questionnaire. The BUS questionnaire is a post occupancy evaluation instrument developed by Building Use Studies, UK. The responses to the variables are sought on a 7-point scale (Thomas and Baird, 2006). In the discussions of survey response means and their standard deviations (SD), reference is made to three types of scale:

- A-type scale where better values are found towards the "right hand" of scale, 1=worst, 7=best
- B-type scale where better values are found towards centre of scale, 4=best
- C-type scale where better values are found towards the “left hand” of scale, 1=best, 7=worst.

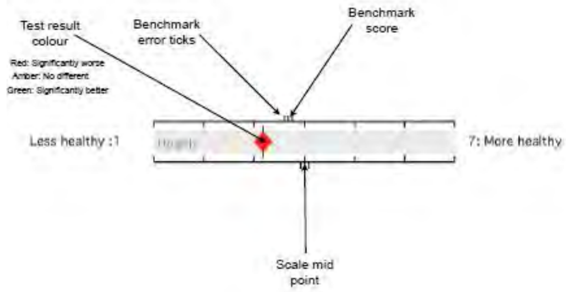

Figure 2. Key to BUS summary charts

The mean value from the survey is assessed against upper and lower limits from the benchmarks for both the benchmark value itself and the scale midpoint. The upper and lower limits are based on 95% confidence level. This creates the criteria for the green, amber or red results for the test as follows: Red diamonds are mean values significantly worse or lower than benchmark and scale midpoint (a poor score). Amber circles represents mean values no different, green squares are mean values significantly better or higher than both benchmark and scale midpoint (a good score). Benchmarks are represented by the three lines on the top scale of each variable and scale midpoint is represented on the bottom as shown in Figure 2 .

A total of 200 surveys were distributed and the respondents were faculty members and under-graduate students totalling 110 individuals whose age ranges from 18 to 45 years. The average weight is 61 kg, average height 1.64 m, 40% males and 60% females. As seen in Figure 3, overall ratings of temperature in summer are significantly lower than the

Midpoint and benchmarks for the case study building (Mean= 2.56, benchmark= 4.58; A type scale).The percentage of dissatisfaction during summer is 80% as per the results and is marked by red diamond in the Figure 2.

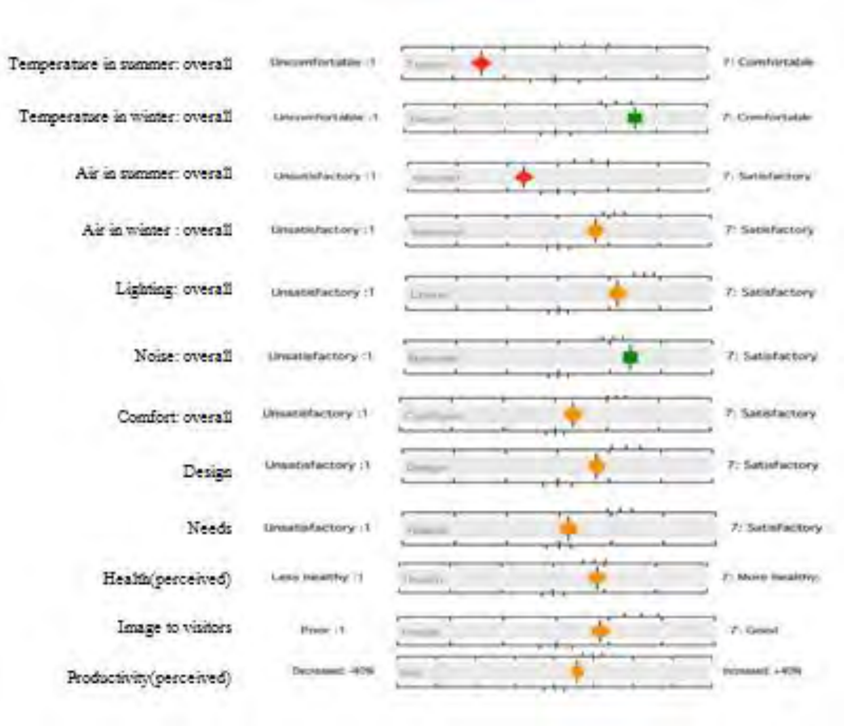

Figure 3. BUS summary chart for case study building.

Computational analysis

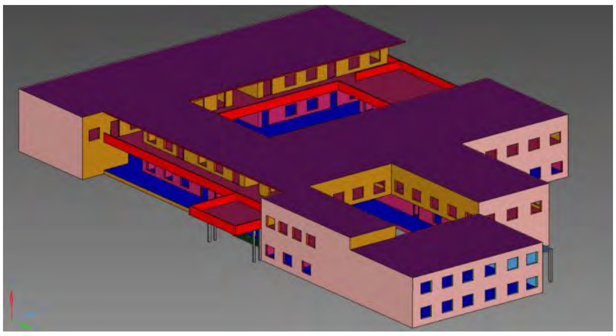

Figure 4. 3D model of the Institutional building for present investigation

The three- dimensional (3D) model of the building (Figure 4) was generated using Autodesk Rivet software and used for CFD analysis. The overall dimensions (Length L, Breadth B and Height H) of the building are 72 m, 44 m and 10 m respectively. The numerical simulation on the discretized domain is carried out using ANSYS Fluent. Standard k-Epsilon turbulence model is used to predict the turbulence and viscous effects. Sufficiently larger flow domain around the building is considered to capture proper building aerodynamics and ventilation. The physical model along with boundary domain is shown in Figure 5.

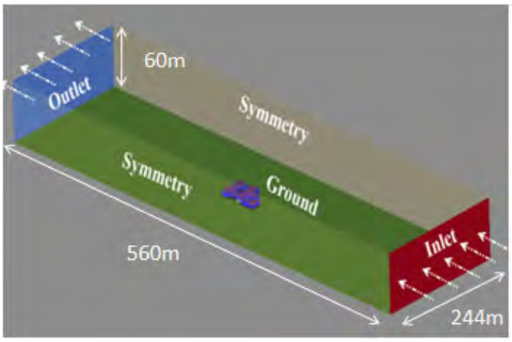

Figure 5. Physical model of the building inside the domain

Figure 6. a. Mesh refinement near the building and portico region, b. Surface mesh refinement near the opened windows

Table 1: Mesh details considered for the present analysis

S.no	Detail	Type	Quality	Count
1	Surface	Tria Elements	Skewness < 60	1.9 Millions
2	Volume	Tetra Elements	Tet Collapse < 0.1	7.4 Millions
3	Nodes	-----------	----------	1.7 Millions

A velocity specified domain inlet is used to indicate the air flow direction and speed. From the recorded outdoor weather data of Madurai, the lowest wind speed of 1km/hr blowing at angle of 254^0 N (southwest direction) and temperature of 37.9^{0}C at 2.30pm on March 24, 2016 was used to calculate the turbulence dissipation rate profiles at the inlet of the simulation domain. The reason for the choosing the data at the above mentioned particular timings was based on considering the BUS survey comments in which the occupants had mentioned that they felt more thermal discomfort during afternoon hours. The pressure is taken as 1.01325 bar. The sides of the flow domain are mentioned with 'symmetry' boundary condition (Fig.5). The building surfaces and ground are given with 'standard wall' boundary conditions. The domain outlet is set with 'pressure outlet' boundary condition. The constant static pressure boundary condition was used at the outlet of the calculation region (Yang et.al, 2014). A boundary domain of 560 m length, 244 m breadth and 60 m height has been selected and the fluid volume is discretized with tetra elements. To solve the governing equations of fluid flow over and through the institutional building, ANSYS Fluent is used. The solver solves Pressure Based Navier Stokes Equations (PBNS) along with turbulence (Jin et.al, 2013, Yang et.al, 2014).

In the present investigation the flow analysis is carried out by considering opened window condition so that the ventilation and airing performance inside the class rooms can be analyzed. The institutional building model is meshed with unstructured triangular elements. A growth rate of 1.9 million has been specified for tria mesh generation from building wall surfaces to the domain. Mesh refinement is given at appropriate locations of the building especially at flow entry zones like windows, doors, etc. Figure 6a depicts the surface mesh and its refinement near the building. Figure 6b shows the surface mesh refinement near the opened-windows and verandas. The overall mesh count created for the present analysis is around 8 millions (Table 1). Unstructured tetrahedral meshes of 7.4 million elements are created around the building. The total number of nodes taken for the computations is around 1.7 millions. The convergence of the solutions is set to 1*e-04. The simulation was carried out in a workstation with xenon processor and 32 GB Ram and it took nearly 72 hours to complete a simulation.

Results and Discussions

As the wind flow direction is from south west with a low speed of 1 km/hr, the pressure rise over the building is not much significant. Figure 7a shows the wind direction and Figure 7b the pressure rise over the rear surfaces of institutional building. It is observed from the numerical simulation that the wake formation in front the building is in cross wise direction as the flow strike angle is inclined to vertical axis of the building in south west direction. This is clearly predicted by the solver as the wake tends towards north east direction (Figure 8). Figure 9a and 9b demonstrates the air flow pattern in the ground floor and first floor. It can be visualized that low wind speed areas (low flow velocities under 0.5 m/s) appeared in most locations due to orientation of windows. The front façade of the building faces east and hence windows facing the east were mostly shaded with corridors as seen in Figure 9a. But some rooms especially on the north western part of the building have windows facing north, west and east. It shows cross ventilation of high velocity air through windows facing west into the studios (Figure 9a & 9b). Since there are no shading devices on the western part of the building, the air entering inside the building will definitely be very hot causing discomfort to the occupants. The simulation results showed variations in the movement of wind in the ground and first floor. Figure 9a and 9b represents the CFD simulation results of velocity magnitude of the ground floor and first floor respectively. It can be observed from the figures that high flow velocity vectors entering the building through windows facing west. Figure 9a represents the velocity magnitude streamlines of the ground floor plan and 9b shows the enlarged view of air flow pattern on the western part of the building.

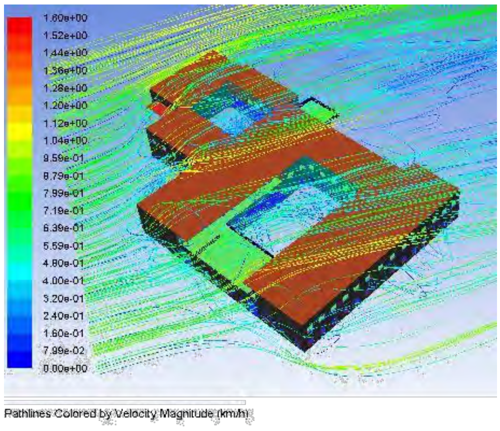

Figure 8. Wake formation and flow pattern around the building

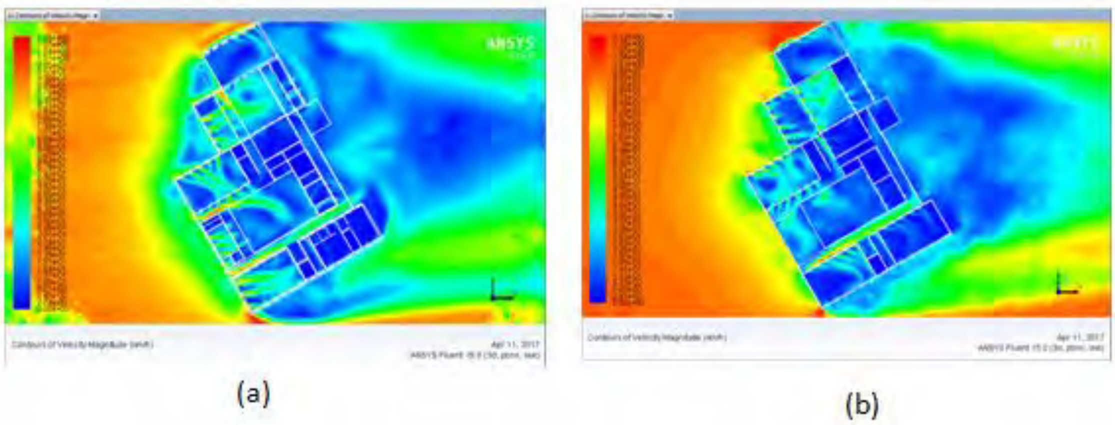

Figure 9. Predicted velocity magnitude contours in horizontal planes at ground floor and first floor level.

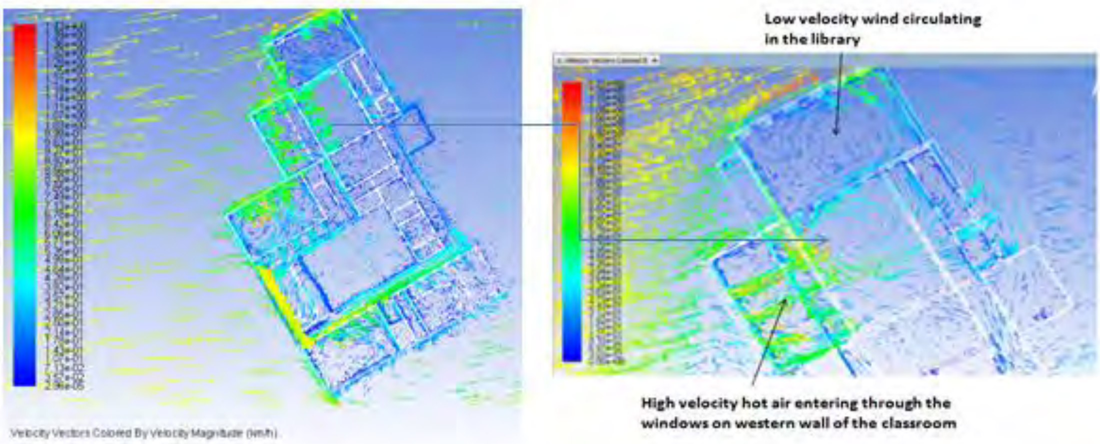

Figure 10. Air flow pattern inside the building at ground floor

Conclusion

In this study, natural ventilation has been investigated using CFD simulation techniques for a low-rise educational building in Madurai. The occupant comfort survey shows that occupants in the building were satisfied with the facilities and building design, except for heat in summer. The simulation results also showed variation in air circulation in the studios and classrooms. Based on the results it showed that a strong movement of air in the north western part of the building, as the plan is staggered with linear walls facing the west. Thus there is possibility of hot air movement from the windows facing west causing thermal discomfort to the occupants. There are also places where weaker recirculation is formed both in ground floor and first floor. Thus the computer results of the airflow properties were very helpful to form a digitized database system for future reference and also to understand the interaction between the building structures and the outdoor wind environment, thereby creating an opportunity to optimize the building envelope design for better thermal performance.

Acknowledgments

I would like to acknowledge Adrian Leaman for permission to use BUS questionnaire under license, and for his feedback and support during the project.

Effectiveness of Natural and Mechanical *Ventilative Cooling* in Residential Building in Hot & Dry and Temperate Climate of India

Devna Vyas[1] and Michael Apte[1]

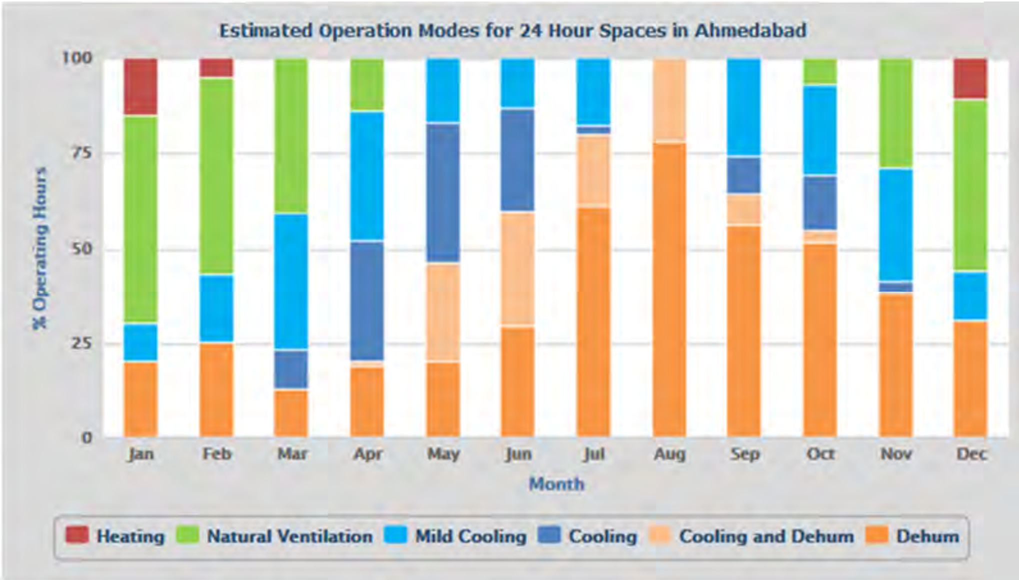
[1] Faculty of Technology, CEPT University, Ahmedabad, India
Correspondence email devna.vyas@gmail.com

Abstract: A residential energy consumption survey of India shows that just 2% of Indian households had air-conditioning in 2007. However, the situation is changing rapidly and the purchase of air-conditioners is showing 20% increase in sales annually. The potential for ventilative cooling to address, in part, these cooling needs has not been sufficiently researched in Indian context and demands immediate attention. This study evaluates the benefit of ventilative cooling techniques in Indian residences. The study first identifies typical single-bedroom apartment plans in multi-family building in India based on past studies and literature. These plans are simulated in DesignBuilder and EnergyPlus simulation models to understand baseline energy consumption. Further, three ventilative cooling design strategies (single-sided natural ventilation, cross-flow natural ventilation, and fan-assisted mechanical ventilation) are designed and incorporated in the residential plans to assess the ventilative cooling benefits. The effectiveness of ventilative cooling is investigated for two representative cities (Ahmedabad, hot and dry; Bangalore, temperate) located in two different climate zones of India. The simulated ventilative cooling benefits are quantified by reduction in cooling hours, reduction in annual and seasonal cooling loads, and reduction in energy use. Further, an hourly heat map for each residence type, for base case (without ventilative cooling), and for various natural and mechanical ventilative cooling strategies, is also prepared for granular comparison. Short-term field measurements of key environmental and building parameters (such as ventilation rates and heat transfer) is conducted in an apartment building to validate key simulation input assumptions. These measurements, supported by physical models, is used to calculate time-averaged ventilative cooling rates. The study provides scientific basis to building designers in understanding the benefits and limitations of natural and mechanical ventilative cooling in Indian residences.

Keywords: Ventilative Cooling, Residential, Natural Ventilation, Mechanical Ventilation, Building Simulation

Introduction

Increasing income and the preference of comfort conditions in India has led to a rapid increase in energy demand for space cooling (Rawal & Shukla 2014). Currently, there are very few residences where mechanical cooling is used; most of the population of India relies on natural, fan-assisted, or evaporative cooling. A residential energy consumption survey of India shows that just 2% of Indian households had air-conditioning in 2007 (McNeil & Letschert 2010). However, the situation is changing and the purchase of air-conditioners is most prevalent in middle class, showing a 20% increase in sales annually (McNeil & Letschert 2010). The potential of cooling with natural ventilation and forced ventilation demands attention and scientific study in order to 1) cater to the need of the larger portion of the population; those who cannot afford air-conditioning and 2) in order to reduce India's energy consumption and reduce its greenhouse gas emissions due to space cooling demands.



Source: (Center for Advanced Research in Building Science and Energy 2016)
Figure 1. Estimated Operation Models for 24 Hour Space in Ahmedabad

Ventilative cooling refers to the use of natural or mechanical ventilation strategies to cool indoor spaces using outdoor air. The most common ventilative cooling technique is the use of increased ventilation airflow rates during cooler outdoor periods, and night ventilation, but other technologies may also be considered. Effectiveness of ventilative cooling is dependent on the availability of suitable ambient conditions to provide cooling to the space. Figure 1 shows estimated operation modes for 24 hour spaces in Ahmedabad based on outdoor climate analysis (Center for Advanced Research in Building Science and Energy 2016). The figure shows that natural ventilation is plausible for seven months (7) of the year for twenty-four (24) hour spaces located in Ahmedabad with November to March period most suitable for ventilative cooling. However, the net benefit of ventilative cooling depends on several factors such as building thermal characteristics, cooling needs, and comfort requirements of the space. This study evaluates the benefit of harnessing cooler ambient air to enhance indoor temperatures without resorting to more energy intensive methods such as air conditioning.

Brief Literature Review

Literature review has been divided in two areas: literature that guide on principles and design of natural and mechanical ventilative cooling, and literature that assess the benefits of ventilative cooling. Engel provides detailed theory of natural and mechanical ventilation based on sun, wind, and buoyancy (Engel et al. 2012) and claims that hybrid ventilation reduces energy consumption of the building for same thermal comfort criteria while also improving indoor air quality. Axley provides a detailed methodology to use natural and hybrid ventilation to cool buildings (Axley et al. 2002) by suggesting three steps to design ventilation system for cooling – suitability analysis, loop equation design method to size ventilation system components and control strategies, and multi-zone coupled thermal- airflow analysis for design development and performance analysis of ventilation system. Similarly, Heiselberg (Heiselberg 2002) and Jicha (Jicha & Charvat 2007) provide detailed overview of hybrid ventilation types, advantages and disadvantages of hybrid ventilation, design tools, examples, and maintenance requirements. IEA-Annex 62 (Kolokotroni & Heiselberg 2015) provide thorough overview of ventilative cooling strategies with detailed description of sizing tools and techniques. The principles, tools, and equations provided have been used as a basis for designing components of ventilative cooling system for typical residential buildings in India.

Salcido conducted extensive literature review of the work conducted in mixed mode ventilation (MMV) area in the past two decades (1996-2016) (Salcido et al. 2016). The study highlighted that up to 40% of HVAC energy consumption can be reduced with natural ventilation in non-residential buildings through window optimization designs and schedules. Liping (Liping & Hien 2007) assessed effectiveness of four ventilation strategies – night time ventilation, day time ventilation, full day ventilation, and no ventilation – in residences located in hot and humid climates. Similarly, Albadra (Albadra & Lo 2014) have carried out a study to quantify the limits of outdoor environmental conditions under which natural (day and night time) ventilation is an effective strategy for achieving thermal comfort along with exploring the effects of certain building characteristics. Aflaki (Aflaki et al. 2016) studied the impact of natural ventilation on thermal performance of a high-rise residential building and advocated use of single side ventilation strategies in residential building.

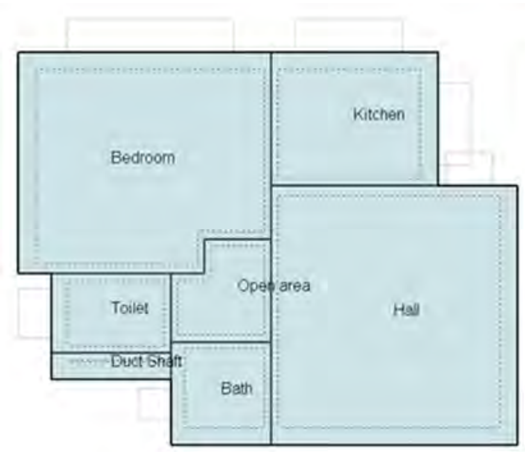
Fu assessed efficiency of hybrid ventilation modes for using two different thermal comfort models - predicted mean vote (PMV) and adaptive thermal comfort model (ACS) (Fu & Wu 2015) and suggested adaptive comfort model as more suitable for ventilation model. Adaptive comfort model proposed in ASHRAE 55 is limited to naturally ventilated building. Manu (Manu et al. 2016) developed adaptive comfort model suitable for mixed mode office buildings in India. This model for mixed mode building has also been adopted by National Building Code (NBC).

There are very few studies that have attempted to study free cooling benefit for buildings in India. Iddon demonstrated that night purge can provide 10% reduction in annual cooling load in an office building located in Pune (Iddon & ParasuRaman 2015). Similarly, Thambidurai (Thambidurai et al. 2015) studied free cooling feasibility of a typical commercial building in Pune and concluded that in a city like Pune with moderate climate free cooling with thermal storage can limit the use of air conditioning system only to three months (March, April, and May). Gradillas (Gradillas 2015) studied the benefits of natural ventilative cooling in hypothetical cube located in Bhuj, Gujarat using DesignBuilder for two design strategies (single-side ventilation and cross ventilation). While the study estimated positive benefits of ventilative cooling, the application of this study can be quite limited due to location specific climate and a small cube design. Thomas (Thomas & Thomas 2014) compares the benefits of natural ventilation in modern apartment buildings in Sydney, Australia and Bengaluru, India. The study concludes that significantly energy savings potential can be achieved if the apartments are designed or retrofitted as per natural ventilation guidelines and principles mentioned in the national building codes (NBC) and residential flat design code (RFDC). While the study provided suggestions on possible natural ventilation strategies for a residential plan and suggested good potential of the same based on climate analysis, it has not simulated or calculated benefits of the approach. No prior study was found that conducted detailed analysis of ventilative cooling benefits in Indian residences. Hence, this paper aims to conduct detailed investigation on cooling benefits of various (natural and mechanical) ventilative cooling strategies in Indian residences located in hot and dry and temperate climate of India.

Methodology

Overall, the study methodology is divided in two parts – simulation and field measurements. Thermal simulation is the primary focus of this paper and has been used to estimate benefits of ventilative cooling in a typical single-bedroom apartment in multi-family buildings. The field measurements are designed quantifying inputs and validating outputs of the simulation models using on-site measurements. Currently, there are no code requirements in India on ventilation or indoor air quality requirements for residences. Hence, benefits in indoor air quality due to natural and ventilation is not scope of this paper.

Typical configuration of individual apartment floor plans of residential buildings is extensively reviewed in two studies based on large number of surveys in India (BEEP 2016; Rawal & Shukla 2014). These studies have also suggested various simulation inputs for typical residential models including appliance penetration, occupancy schedule, and envelope construction for a typical multi-family residential building in India. The studies also highlight that the Indian residences are designed for zoned mixed mode where an air conditioning system is typically installed only in the bedrooms. Further, the air-conditioning system in the bedroom operates in change-over mixed mode where the system runs only during extreme weather periods. DesignBuilder uses EnergyPlus AIRNET method to calculate airflow rates from openings and assumes all openings to be vertical. A model of a single bedroom apartment was created in DesignBuilder to estimate benefits of ventilative cooling. Figure 2 shows building plan in DesignBuilder and key simulation inputs used in thermal simulation model:



Envelope Construction and Thermal Properties	
Wall	12mm Outside Plaster + 230 mm brick wall + 12 mm Inside Plaster U-Value - 1.722 W/m2-K
Roof	10 mm Tiles + 12mm Plaster + 150 mm concrete roof + 12mm Plaster U-Value - 2.942 W/m2-K
Window	Single Glazing with Aluminium Frame 22% Window to Wall Ratio (as per plan) U-Value - 5.8 W/m2-K, SHGC - 0.82, VLT – 0.8
Floor	10 mm Tiles +12mm Plaster + 150 mm concrete roof + 12mm Plaster U-Value - 2.942 W/m2-K
Zone Area, Operation Schedule, Occupancy and Internal Heat Gains	
Bedroom	Operation: 10 pm to 7 am, Internal Gains (lighting + equipment): 320 Watts, Occupancy: 2 people, Area: 9.6 m2
Living Area / Kitchen / Others	Operation: 7 am to 10 am and 7 pm – 10 pm, Internal Gains (lighting + equipment): 800 Watts, Occupancy: 2 people, Area: 20.4 m2

Figure 2. Single-bedroom Apartment Plan and Thermal Simulation Inputs

Figure 3 shows simulation run chart containing forty simulations per each climate zone where impact of climate zones, orientation, and ventilation strategies has been assessed against a reference case. Ahmedabad (located in hot and dry climate) and Bangalore (temperate climate) has been selected as a representative city for hot and dry as well as temperate climate. Since IMAC comfort model is specifically developed for mixed mode buildings (Manu et al. 2016), and considering lack of alternative models that can be applied to residences in India, the adaptive thermal comfort model has been applied to assess comfort and to determine cooling needs.

In parallel, ventilation rates under no ventilation, natural ventilation, and mechanical ventilation strategies is measured in one bedroom of an unoccupied two-bedroom apartment. For continuous ventilation measurements in the apartment, a novel tracer gas method was developed and tested for cost-effective yet real time air exchange rate measurements. In this method, a block (approximately 10 kg) of dry ice is placed in an insulated cooler on a precision weighing scale inside the space and allowed to slowly release carbon dioxide (CO_2) in the space at a measured rate. Concurrently, a calibrated CO_2 sensor continuously measures CO_2 levels in the space. Using mass conservation, the ventilation rates are continuously calculated for each measurement period. These field measurements are not aimed to provide thorough validation or to calibrate simulation models but to derive realistic input assumptions.

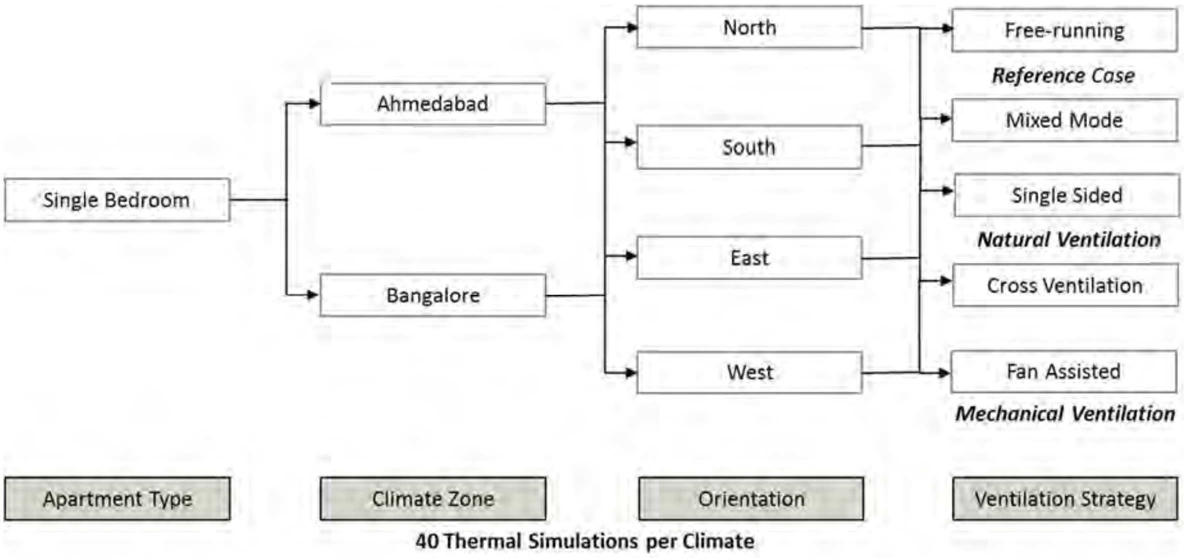


Figure 3. Simulation Run Chart

Sizing of Ventilation Components

Natural ventilation opening and mechanical fan flow rates for one bedroom apartment were determined in three steps: (1) calculate the period when ventilative cooling could be useful, (2) calculate flow rate requirements for the space, and (3) size opening and mechanical fan flow. To determine period when ventilative cooling can be useful, thermal simulation of the above described prototypical one bedroom apartment is run in the free-running mode. The space operative temperature (OT), which is arithmetic mean of air temperature and mean radiant temperature, from the simulation is compared against the adaptive setpoint (AS) and outdoor temperatures (OAT) to determine the period when ventilative cooling can be useful. Based on the comparison, Figure 4 shows when the outdoor temperature is too cold (blue), is beneficial for ventilative cooling (green), and is too hot (Red).

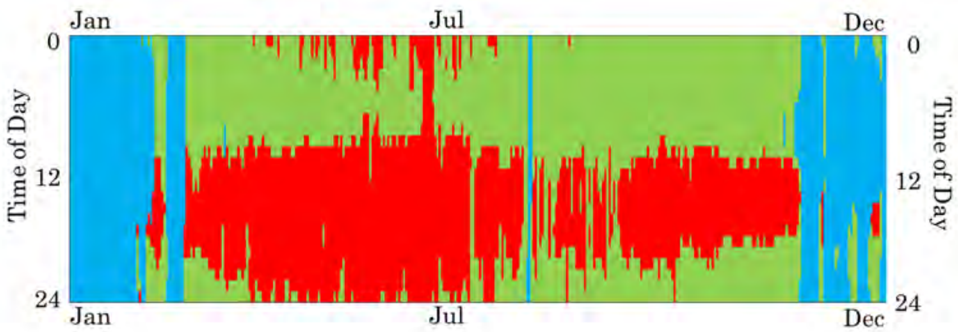

Figure 4. Simulation of 1BHK Residential Apartment in Free Running Mode to Determine Building Operative Temperature – North Orientation in Ahmedabad

Ideal flow rate for the ventilative cooling is calculated for each hour using the following method:

$$Air\ Change\ per\ Hour\ (ACH) = \frac{Flow\ Rate}{Volume} = \frac{1}{V_{room}} \times \frac{[\rho_{air} V_{room} C_p (T_{room} - T_{setpoint}) + Q_{internal}]}{\rho_{air} C_p (T_{room} - T_{outdoor})}$$

Where, ρ_{air} is density of air, C_p is specific heat of air, V_{room} is space volume, T_{room} is room temperature, $T_{setpoint}$ is setpoint derived from IMAC adaptive comfort equation (Manu et al. 2016), $T_{outdoor}$ is outdoor air temperature, and $Q_{internal}$ is internal heat gain. A flow rate of 3 air change per hour (ACH) was found to meet ideal flow requirements for 88% of the hours when ventilative cooling is useful. Hence, mechanical fan for bedroom (of 30 m^3 volume) is designed to provide 90 m^3/hour for ventilative cooling. The fan is turned on only during the period when ventilative cooling is effective. Following equation is used to determine natural ventilation opening size for each hour:

$$A = \frac{q}{C_d} \times \sqrt{\frac{\rho}{2\Delta P}}$$

Where, ρ_{air} is density of air, C_d is coefficient of discharge (0.61), q is ideal flow rate, and ΔP is pressure difference across opening (due to wind and stack). Using above equation, ideal effective opening area is calculated for every hour throughout the year (similar to ideal flow requirement). Wind velocity and direction is obtained from TMY3 weather file for Ahmedabad and Bangalore. Based on the analysis, an opening area of 0.5 m^2 in Ahmedabad and 0.4 m^2 in Bangalore could meet ideal flow requirements for 85% of the hours when ventilative cooling is useful. Opening area is added in the simulation model to determine ventilative cooling benefits.

Results and Discussions

The simulation results are compared using two metrics – uncomfortable hours and reduction in thermal cooling needs of the space. The operative temperatures from simulation results are extracted and compared with the IMAC adaptive comfort setpoints (Manu et al. 2016) to determine the uncomfortable hours for free-running mode and for each ventilative cooling strategies. To determine reduction in cooling thermal needs, the annual delivered system cooling is extracted from the simulation models for mixed mode operation and each of the ventilation cooling strategies. Figure 6 shows summary results for reduction in uncomfortable hours and thermal cooling needs of the space.

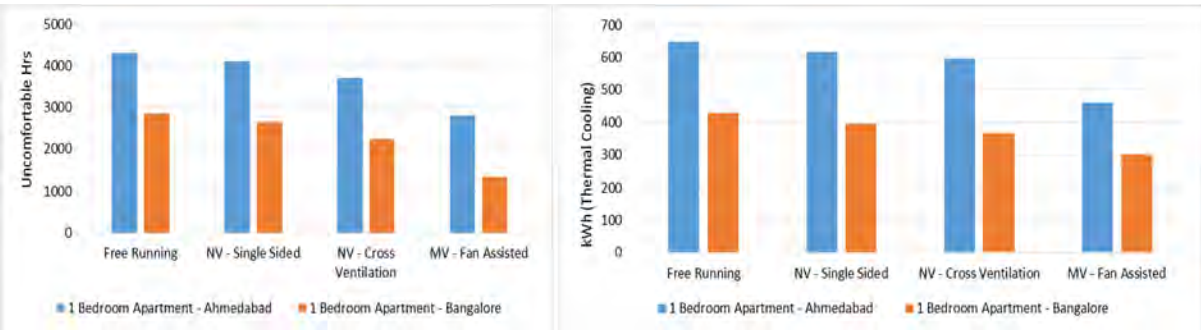

Figure 5. Annual Ventilative Cooling Benefits for Ahmedabad and Bangalore

Calculating from data shown in Figure 6, natural (NV) and mechanical ventilation (MV) can reduce uncomfortable hours by 10-12% and 21-40%, respectively, as compared to free-running mode. Similarly, natural and mechanical ventilation can reduce thermal cooling needs of the space by 12-14% and 30-35%, respectively, as compared to mixed mode operation. The ventilative cooling benefits are 2-10% higher in temperate climate as compared with hot and dry climate. Further, the orientation plays important role for natural ventilation savings but have marginal impact on savings due to mechanical ventilation. The ventilative cooling benefits are slightly higher (3-5%) for cross-ventilation as compared to the single-sided ventilation.

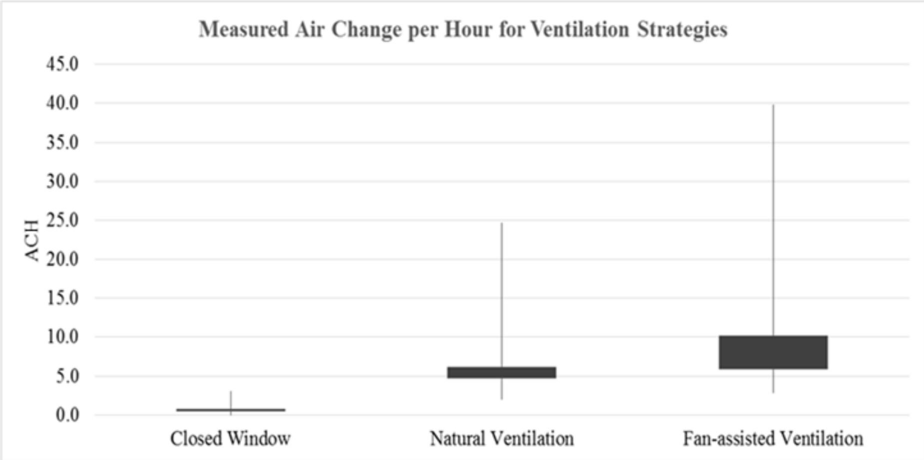

Figure 6. Field Ventilation Measurements for Ventilation Strategies

The measurements were conducted for a period of 30 days in the month of March and April. Data were recorded for three modes; free running, natural ventilation, and mechanical (fan-assisted) ventilation in random order during the course of measurement period. Figure 7 shows measured ventilation measurements in the apartment building for three ventilation strategies.

The closed window mode where there is no natural ventilation happening, the air change as a result of infiltration shows the values of 0 - 2 ACH with the average value of 1 ACH. In the natural ventilation mode when the windows are open from morning to evening, the ACH values varies between 2.5 to 25 ACH and the average value is observed to be 6 ACH. For the fan-assisted mode, where a fan is kept on inside of the open window, the ACH values vary between 3 ACH to 40 ACH sometimes with an average value observed to be around 8 ACH. The variation in measured ventilation rate is high for natural and mechanical ventilation strategies and need further investigation on the causes of the variation.

Conclusions

The results demonstrate the potential for natural and mechanical ventilation strategies to be effective for single-bedroom residences in India providing 10-14% reduction in uncomfortable hours and 21-40% reduction in annual cooling needs. While ventilative cooling is more effective in temperate climate, significant benefits can be achieved even in hot and dry climate of India during night periods.
A novel method to continuously measure ventilation rate is developed for affordable yet accurate measurements. Short-term field measurements (of 30 days) showed that no ventilation, natural ventilation, and mechanical ventilation yields 1 ACH, 6 ACH, and 8 ACH, respectively. Future research will include more field measurements, different typology of apartments (2 bedroom and 3 bedroom), granular analysis of benefits, and more ventilation strategies (stack ventilation at building level). Further improvement in method can increase robustness of the method.

Winter Indoor thermal environment investigation in apartments at a central China city and Dutch Eindhoven

Yin Wei[1,2] , Jie Han[1], Hui Chen[1], Guoqiang Zhang[1], Zhaonan Xu[1]

[1] College of Architecture, Hunan University, Changsha, Hunan 410082, China
[2] School of Civil Engineering, Hunan University of Science and technology, Xiangtan, Hunan, China

Abstract: This paper intends to use an example to reveal some realities of indoor thermal environment in residential building of central China, and compare that with Europe. People living in the Humid Subtropical Climate of central China often complain of the cold indoor environment during the winter, despite their use of heating appliances. To address this issue, this study conducted an investigation on two indoor thermal environments during the equivalent-time periods. The first in a typical apartment in Xiangtan, a city of central China, and the second in the city of Eindhoven, which is located in southern Netherlands. The former was conducted from November to January, and the latter was from February to March. It was found that the indoor temperature of the apartment in China was between 14-20°C, in comparison to 20-24°C in the apartment of Eindhoven. In addition, the apartment located in Eindhoven yielded larger differences between the moisture content inside the building and outdoor environment, indicating that the building was better air-tight than Xiangtan's. This is a common problem with residential buildings in this location in China. An air-tight building is required for heat-isolation, and is a suitable direction to take when retrofitting existing residential buildings to obtain better indoor environment in this climate zone. Furthermore, the indoor thermal situation representative in this climate zone of China might not be in the range suitable for adaptive thermal comfort.

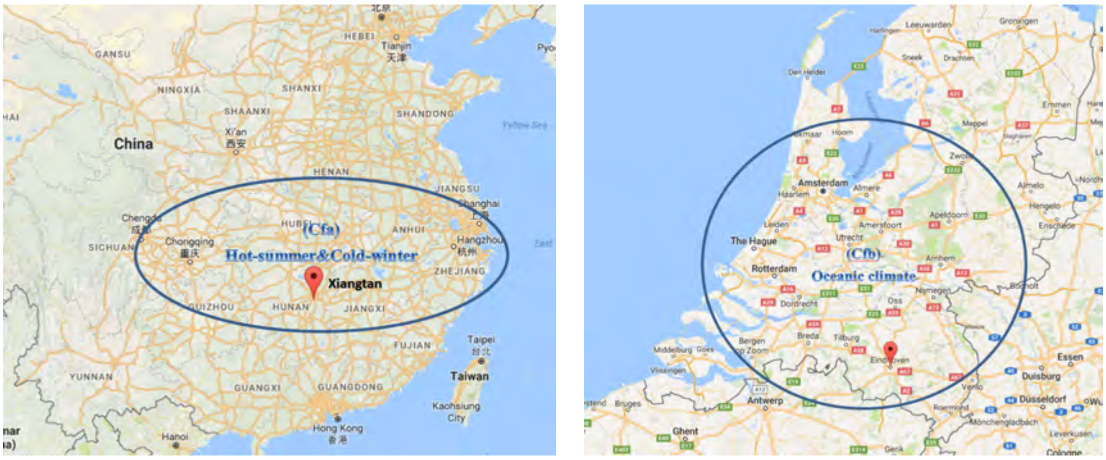
Keywords: Winter indoor environment, thermal comfort, hot-summer and cold-winter (Humid Subtropical Climate), residential buildings retrofitted, difference between Europe and China

Introduction

Indoor thermal environment during the winter is a significant factor to occupants' health and thermal comfort. Although it seems a traditional topic, many buildings in China and across the world still suffer from the issue of unsuitable indoor temperature in residential buildings.

Kuchen, E. and M. N. Fisch (2009) surveyed the thermal comfort of the occupants in 25 office buildings during the winter in Germany, with measured data and the subjective data, by which it was found that the persons can accept a neutral temperature near the imposed pre-established value of the operative temperature. Zeiler, W. and G. Boxem (2009) focused on the thermal comfort of the schools in the Netherlands via measurements and questionnaires held in 14 schools, equipped with different types of ventilation and heating systems. It was found that Thermo-Active Building Systems, an new systems combined with natural air supply and mechanical exhaust, could produce a small improvement of perceived thermal comfort at school buildings in winter. Kavgic, M., et al. (2012) investigated winter indoor temperatures, relative humidity and vapour pressure across 96 representative dwellings at Belgrade in southern Europe. It was found that district heating produced a high degree of overheating, which is an issue for future work to solve to increase the energy efficiency of buildings. Luo, M., et al. (2014) investigated 139 residential apartments in Beijing and Shanghai, and found that occupants with the capability of individual control over space heating systems had a 2.6 °C lower neutral temperature than those without personal control. Yu, Z., et al. (2015) recommended that the temperature range for temporarily occupied space, such as supermarkets, to be 16.9 °C -17.4 °C at Tianjing near Beijing, in the cold climate region of China, based on results of experiment in a climate chamber.

China’s central zone is located in the climate area named hot-summer and cold-winter climate zone(HSCW), which is defined as Humid Subtropical Climate (marked as Cfa) in Köppen-Geigers system of climate classification, shown in in Figure 1a. More than 400 million people, one-third of Chinese nationality, live in the region shown in blue circle in Figure 1b. The average temperature in winter is around 5 °C, which is much higher than northern China. However, occupants living in the specified region complain of the cold during the winter, even though there are heating supplied by air-heat-pump from air-conditioning systems.



(a) (b)

Figure 1. Climate regions where two cities located.

Some research has been conducted to shed further light on the winter indoor thermal comfort in the Humid Subtropical Climate region of China. Lin, B., et al. (2016) found that the average internal temperature in the HSCW region of China is 13.5 °C for the living room, and 12.7 °C for the bedroom, producing an uncomfortable indoor thermal environment, markedly colder than that in the UK as similar winter climate, who experience temperatures of 19 °C. Cao, B., et al. (2016) conducted a comparative winter thermal comfort field study in Harbin(46deg.NL), Beijing(40deg.NL) and Shanghai(31deg.NL), which represented the Severe Cold zone, Cold zone, and Hot Summer & Cold Winter zone respectively. It found that the indoor temperature in Shanghai exceeded 80% in the temperature range of 16–22 °C, which is lower than those experienced in Harbin and Beijing with district heating supplied indoors. In addition Shanghai’s percentage of acceptance is higher than Beijing but lower than Harbin.

Some work has been conducted to provide a comparison to indoor thermal comforts between China and Europe. Zhang, N., et al. (2018) compared winter indoor thermal environments in two northern cities, Beijing and Harbin, with other 8 cities from South Europe and North America, all in a similar latitude range. It was found that Chinese cities had a lower temperature than European and North American cities, and that their neutral temperatures were 21.7℃, 23.4 ℃ and 22.7 ℃ respectively [8].

Until now, there have been few research studies conducted comparing the indoor thermal environment of residential buildings during the winter, between central China and western Europe, in which climate found in the Netherlands represents a typical European climate marked as Cfb in Köppen-Geiger with warm, temperate and rainy weather, and its winter around 3 ℃, shown in Figure 1b. During the winter of 2016-2017, a family of 4 persons including the author moved from an apartment located at Xiangtan central China to Eindhoven southern Netherlands. All people in this family feel much more comfortable indoor climate in Eindhoven than Xiangtan, where even they had resided for 20 years. Similar equipment had been used to record the field data and find out the direct reason behind occupant discomfort.

Survey methodology

An investigation was undertaken from Nov. 27 of 2016 to Jan. 9 of 2017 at a Xiangtan's apartment located on the 6th floor of a residential building (7 storeys high), which was built in 2005. A second survey was employed from Feb. 8 to Mar. 12 of 2017 in a second-floor apartment at a building more than 80 years old in Eindhoven, but retrofitted in (year) to include an individual central gas-heating system. Both of them represent their local indoor thermal environment individually.

In Xiangtan's apartments, a Logger was recording temperature and relative humidity placed outside the south window with a recording interval rate of five-minutes, depicted in Figure 2. Then the same Logger was used in Eindhoven, from Feb. to Mar. of 2017. Thus, some of following figures show the data of difference cities at one successive profile, in which the early part is the China and the later part is Eindhoven. So do another Logger in bedroom.

Xiangtan Eindhoven

Figure 2. Apartments at central China and northern Netherland.

It needs to be highlighted that during daytime when the recording equipment was placed on the windowsill, it was recording partly the operative temperature combining air dry-bulb temperature and solar radiation due to its direct exposure to the sunlight. The diversity between outdoor operative temperature and dry-bulb temperature was analysed as part of the daily analysis, in which outdoor dry-bulb temperature was acquired from the online weather data of the Weather Company (2017).

Data analysis

Winter outdoor climate

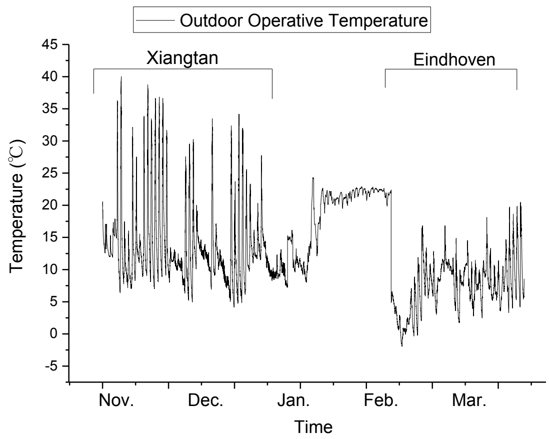


Figure 3. Outdoor operative temperatures at Xiangtan of China and Eindhoven of Netherlands.

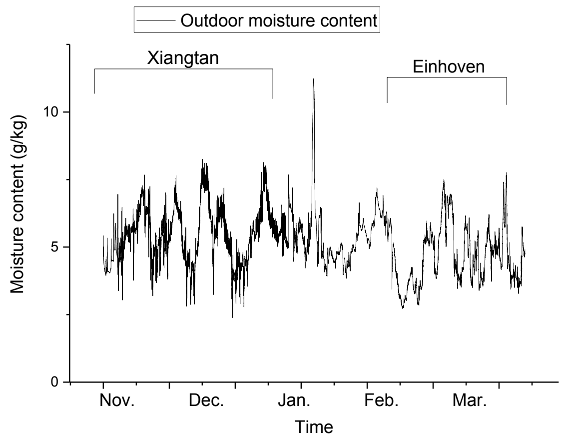

Figure 4. Outdoor moisture content at two cities.

As calculated from the field data, the neutral indoor operative temperature during the winter in Xiangtan was 13.2 °C, and 7.6 °C in Eindhoven, which indicates that Xiangtan has a warmer outdoor environment than Eindhoven. In Figure 3, it is illustrated that the amplitude of operative temperature fluctuation in Xiangtan was higher than in Eindhoven, as well as experiencing large fluctuations, which means the stronger solar radiation is occurring in central China than in the southern Netherlands.

In figure 4 the outdoor moisture content calculated from temperature and relative humidity is provided. The left and right elements of the moisture content profile in figure 4 revealed similar shapes and levels in both Xiangtan and Eindhoven, with a mean moisture content 5.5g/kg and 4.7 g/kg respectively.

Indoor thermal environment

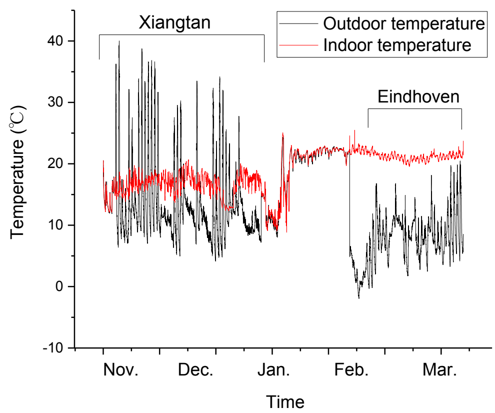

Figure 5. Indoor dry-bulb temperature.

In bedroom of apartment at Xiangtan, air-heat-pump heating from air-conditioning system was working during most of winter occupant time. At Eindhoven the central gas-heating system was working whole day. Figure 5 indicates that the indoor temperature is under 20 °C during most of time in China, in comparison to above 20 °C in Dutch.

Indoor temperature is more fluctuant in Xiangtan. On the one hand, the variance of Xiangtan's data is 2.8, and Eindhoven is only 0.4. On the second hand, figure 6 illustrated that Xiangtan's 91% temperatures are among 14 °C to 20 °C(23%+48%+19%)). Eindhoven's 97% temperatures are among 20°C to 24 °C, in which 20°C to 22 °C occupies 89%.

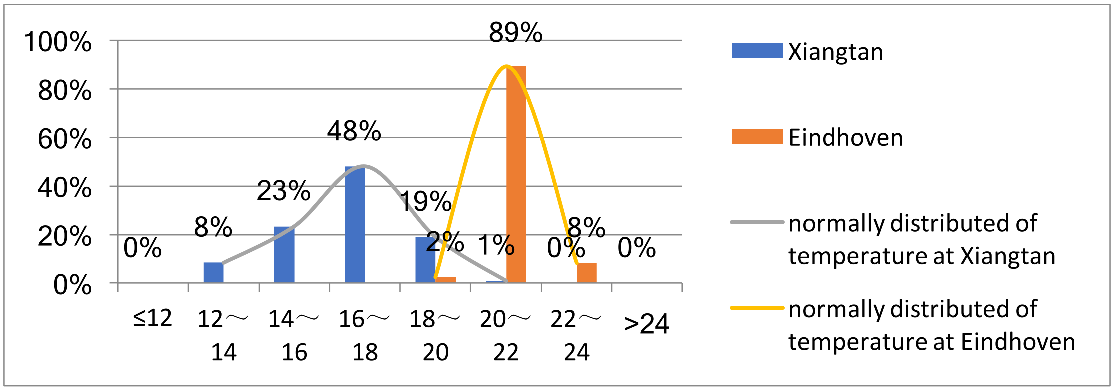

Figure 6. Distribution of indoor temperature.

The lower and more unstable indoor temperature is not only due to underpowered heating supply, but also bad insulation and airtight. Although this is only a case study, it represents the typical phenomena of low temperature in this region of China. Therefore local people have to wear thick clothes to keep warn.

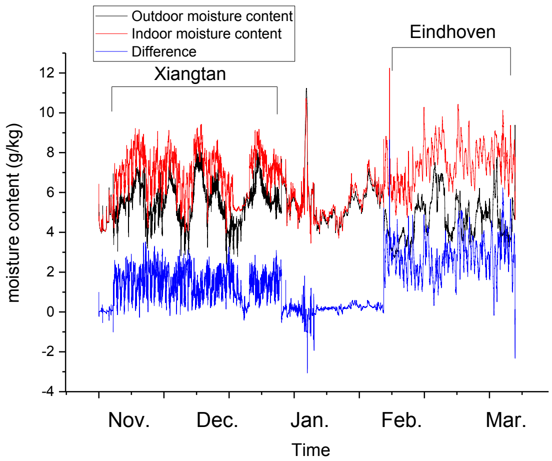

Figure 7. Indoor moisture content.

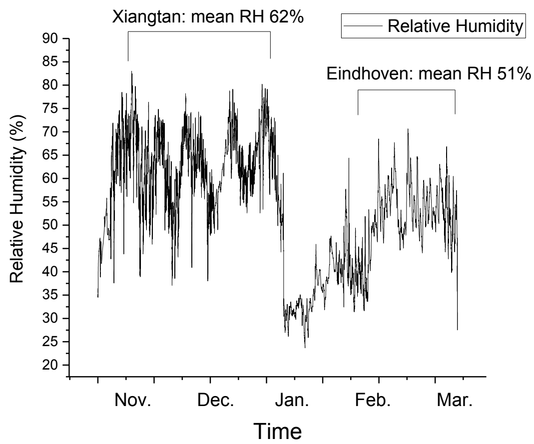

Figure 8. Indoor relative humidity

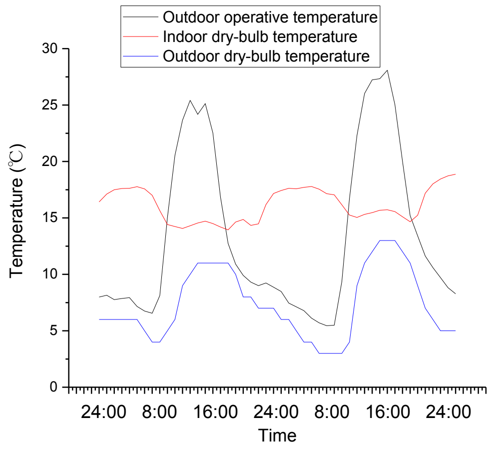
As shown as figure 7, the indoor moisture contents at Xiangtan are at approximate level as Eindhoven. From calculation, the mean value of the former is 6.9g/kg similar to the latter 7.5 g/kg, as well as former variance 1.11 to latter 1.04. Nonetheless the former is smaller at moisture content difference, between indoor and outsiders, at 1.4 g/kg, in comparison to the latter's 2.8 g/kg. It may be that the residential building in China has worse airtight. Because it needs much natural ventilation to dissipate heat during spring, summer and fall, there are cracks around windows and doors.

Figure 8 indicates that it is dryer in Eindhoven than Xiangtan, which might be a reason causing comfort feeling.

Daily change of indoor thermal environment

Typical daily indoor temperature



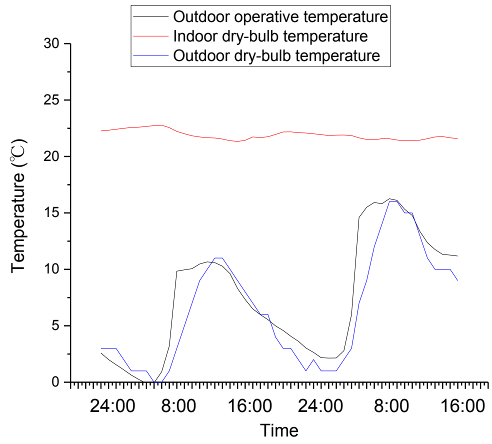


Figure 9(a). Indoor temperature during Dec. 15-16 of 2016 at Xiangtan.

Figure 9(b) Indoor temperature during Feb. 14-15 of 2017 at Eindhoven

Figure 9(a) draws the profiles of indoor dry-bulb temperature, outdoor operative temperature, and dry-bulb temperature, during two-day of Dec. 15-16 of 2016 at Xiangtan. 9(b) provides the same parameter during Feb. 14-15 of 2017 at Eindhoven. They were both sunny during these days.

Shown in Figure 9(a), the outdoor operative temperature is much higher than indoor dry-bulb temperature at most of daytime. However, it isn't happen at Eindhoven in Figure 9(b). Its outdoor operative temperature and dry-bulb temperature are very approximate hour by hour. This implies Xiangtan has stronger solar radiation than Eindhoven during the winter's sunny days.

It is observed that in Figure 9(a) that the profile of indoor temperature of daytime is a little bit lower than night-time. This is due to nobody home and heating system is not working.

According to statistics during two days, Xiangtan's indoor temperature varies from 13°C to 19 °C, nearly 6 Celsius gap. Eindhoven is at interval of 22 to 26 °C. Their average outdoor temperatures are 6.4 °C to 7.4 °C respectively. This is according with their trends of whole season data.

Daily indoor moisture content

In figure 10, the Eindhoven's curve has two peaks when the sleeping time. However Xiangtan's varies irregularly. In figure 11(a), the absolute humidity of indoor and outdoor during night-time seems having the similar trend. But in figure 11(b) there is less similarity of them. This as well could be proved from correlated coefficients between indoor and outdoor moisture content in Table 1, China 0.59 to Netherlands 0.37. It may mean that the Chinese resident building has worse airtight.

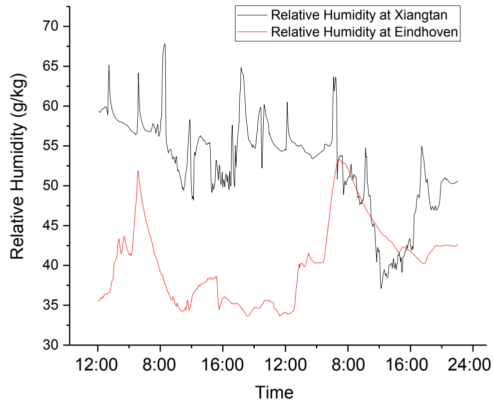

Figure 10. Indoor relative humidity of two days at Xiang and Eindhoven.

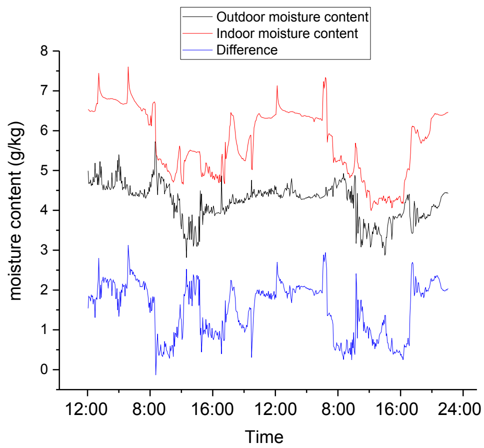

Figure 11(a) Indoor moisture content during Dec. 15-16 of 2016 at Xiangtan

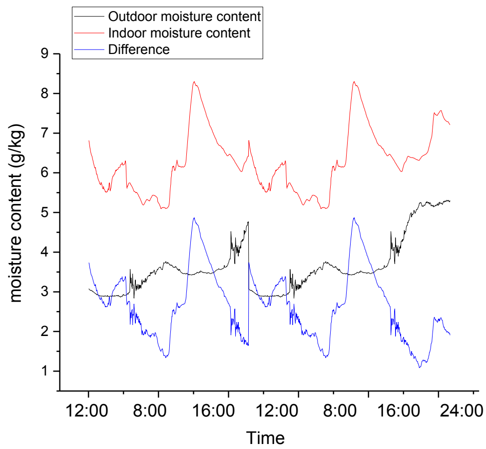

Figure 11(b) Indoor moisture content during Feb. 14-15 of 2017 at Eindhoven

Table 1 Correlated coefficients between indoor and outdoor moisture

	Indoor mean moisture content g/kg	Outdoor mean moisture content g/kg	Difference g/kg	Correlation Coefficient
Xiangtan of China	5.74	4.22	1.52	0.59
Eindhoven of Netherland	6.34	3.79	2.55	0.37

Conclusion

The focus in this study is to employ a preliminary investigation to realize real indoor thermal environmental situation at central China and western Europe. It is found:

1, although Xiangtan's outdoor operative temperature is higher than Eindhoven, its indoor temperature is colder than latter with 5 °C during winter. And the fluctuation of temperature is another obvious issue to comfort of occupants.

2, the Chinese apartment's moisture content difference between indoor and outdoor is much higher than European. In general this comes mainly from bad airtight, but it needs further study to make certain its exact contribution in comparison to other factors, such as porosity of building materials and absorption of vapours, heating operation and occupation patterns etc.

Even though the investigation and analysis given has much limitation because only two apartments from China and Europe have been compared, it reveals the thermal situation in residential buildings at central China. Despite this Chinese family's people had lived there more than 20 years, they still could complain their indoor thermal environment. But when moved to Netherland, they felt much comfortable in the warmer and stable indoor climate.

In terms of thermal comfort, this study has same conclusion as Lin, B., et al. (2016) with uncomfortable of too cold. The difference is that here it has higher indoor temperature. It has similar indoor temperature range as Cao, B., et al. (2016), but here occupants feel too cold. It indicates the occupants feel cold that different from much lower acceptable indoor temperature from Han, J., et al. (2007, 2009). All of these need further study.

A new trend happening in this area is that more and more families prefer to install high-power household heating system by gas or electricity, and then it will consume much more energy than before. But the energy consumption would be probably higher than northern China due to worse thermal insulation and airtight. In a word, improving the performance of existing buildings should be the priority in hot-summer and cold-winter region of China.

Optimising Residential Courtyard in Terms of Social and Environmental Performance for Ghadames Housing, Libya

Jamal Alabid[1], Ahmad Taki[2]

[1] Architectural Research Group, Leicester School of Architecture, De Montfort University Gateway LE1 9BH – UK jamal.alabid2@dmu.ac.uk
[2] Leicester School of Architecture, De Montfort University, Leicester LE1 9BH UK ahtaki@dmu.ac.uk

Abstract: Vernacular architecture comes from a wealth of knowledge and experience of humans who were able to adjust to the surroundings and adapt to even extreme climate conditions. In fact many old traditional settlements may fail to functionally provide high indoor quality according to the modern building standards. However, these buildings are still seen as a good example of serving the purpose of locals' social life and their ability to effectively respond to outdoor climate. Therefore, this work recognises the need to develop the courtyard concept to meet the social and environmental requirements of today's housing conditions taking the advantage of traditional architecture of Ghadames. The work carried out methods of descriptive and simulation analysis to investigate the environmental performance of existing and proposed residential courtyards employing natural ventilation system in terms of thermal comfort conditions. The optimisation process of the courtyard design not only relied on methods of observation but also householders and professionals' views were considered. Householders and professionals agreed that courtyard houses might be often linked to lower social classes but still serve most of social and climate purposes. The dynamic thermal simulation showed that indoor comfort temperature in a traditional courtyard was found to be at 34˚C. An optimisation design process was conducted to a courtyard building resulted in reducing the indoor comfort temperature to about 28˚C. Further results showed that the new design has improved the daylighting performance at 2.9% of average daylight factor. The work also outlined the applicability of using locally sourced building materials and their capacity to achieve high thermal performance particularly with reference to the use of organic date-palm fibre. It can conclude that the proposed design has integrated the passive climate design strategies to help achieving acceptable indoor comfort conditions and also sustainable features to further enhance locals' social life.

Keywords: Climatic design, EnergyPlus, courtyard house, indoor human comfort.

Introduction

Courtyard housings proved to be one of the best solutions in hot arid settlements and have been developed through experience of trial and error by local builders to serve social and cultural needs (Coch, 1998; Majid et al., 2012). Among a number of research group including Naciri (2012) and Nikpour et al. (2012) the role of the central courtyard in traditional architecture acting as a climate modifier was recognised and considered to be the best residential form in delivering sufficient natural ventilation and daylighting for interiors especially in hot regions. However, it has not been clearly identified in practice how such traditional techniques can be implemented in modern architecture (Bekleyen and Dalk, 2012).

The energy and environmental performance of courtyard buildings has been investigated and well documented in literature including Ben-Hamouche (2008), Al-Masri and Abu-Hijleh (2012) and Mandilawi (2012) who found that a great energy reduction of 54.25% can be achieved compares to conventional building forms. The abandonment of traditional wisdom and knowledge and the partiality of globalisation by many people to imitate western development and selection of inappropriate design and materials led to unsustainable and unaffordable constructions especially in developing countries (Bruen et al.,2014). Therefore, developing new forms of residence that take advantage of local context and new available technology will be the way forward to deal with social and environmental aspects as well as todays' world challenges including energy and nature conservation issues.

Comfort and social needs are the main issues taken into account for optimising the residential courtyard of Ghadames housing and consequently its impact on total energy consumption. The internal centred courtyard is the most common type used in hot arid climate bringing many benefits including reduction in energy and noise, possibility of enhancing the indoor visual environment by opening windows into it and protection from outdoor harshness (Vaisman and Horvat, 2015). As reported in many studies including Abarkan (2000) and Nikpour et al. (2012) the courtyard in residential traditional architecture was an outcome of cultural as well as climatic aspects. However, the courtyard concept was developed and saw radical transformation by the 20th century in Libya as a result of life change and western culture influence (Bilghit 2007).

Research methodology

The research is carried out through methods of observation, interviews and dynamic simulation analysis. A case study of a traditional house was selected to investigate indoor thermal and design conditions of old settlements of Ghadames particularly the social and environmental role of central courtyard. The strategy was to conduct field surveys including temperature measurements during the interviews and simultaneously observe any phenomenal aspects. These aspects may be related to techniques used for ventilation, daylighting or occupants' behaviour supported by drawings, sketches and photos. EnergyPlus is used to first verify field data and test proposed courtyard performance.

The case study climate characteristics

Ghadames lies in the hot arid desert climate characterised with very low precipitation and far less than the potential evapotranspiration with large temperature swings in the daily cycle especially in summer resulting in low humidity rates. The city falls in the most extreme zones within the Libyan climates as located in the Sahara Desert region with almost eight months of hot and dry period and four moderate and partly cold winter period (Zifan, 2016).

Typical traditional house

Old settlements of Ghadames generally were designed to reduce exposure to outdoor conditions and enhance air movement through maximising shadings on buildings and street levels. The majority of traditional houses consist of three storeys and attached wall-to-wall from four sides creating very compact form. Streets and pathways are either fully or semi-shaded covered by first floor extended roofs. The form of the house combines high degree of compactness with minimum exposure to outdoor and relatively small plot area ranges from 25 to 50 m^2. The space organisation of rooms varies according to the privacy level and functionality though. It is therefore constructed in three storeys to accommodate fully-sheltered ground floor consists of usually main entrance with stairs, guest room, storage and cesspit room. The first floor is a semi-private family area centralised by living-room which is surrounded by number of rooms.

The central hall is constructed in double-volume height with steps leading to mezzanine level which also consists of other private bedrooms. Stairs lead up to the roof level where kitchen is found as well as summer shed space used so often at summer nights. In Figure 1 the central living hall represents the inner courtyard of traditional houses which located in the heart of the house built in double ceiling height (4-5m). The 1m^2 roof aperture placed in the central living hall is the main source of daylight and natural ventilation for surrounding rooms. Hence, families spend most of their time in this hall and also practising many social and religious occasions.

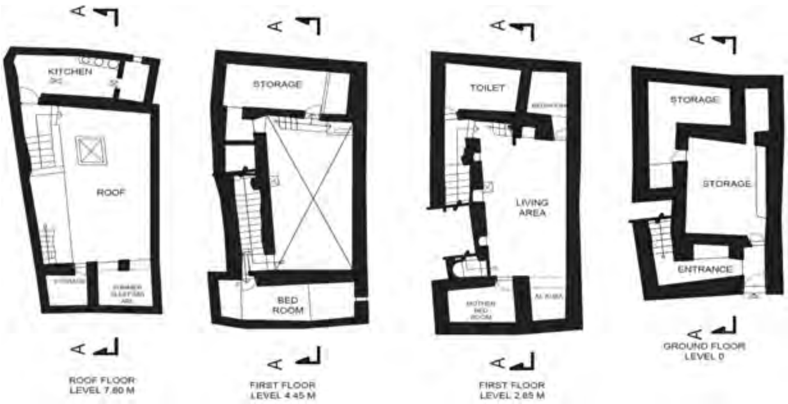

Figure 1. Plans of typical traditional house in the old town of Ghadames

Construction materials

Rocks and mud are the most common building materials in the old town of Ghadames settlements due to the nature of the desert land (Al-Zubaidi, 2002). Rocks are used in foundations and on ground floor for only the first 1.5m height. However, traditional houses constructed not only with sun-dried mud and stone which is mainly used in the bearing walls but also gypsum, limestone and wood are commonly used particularly in roof construction and finishing. Technically, walls are made out of sun-dries mud bricks with approximate digestions of 12×40× (75, 60 and 50) cm as shown in Figure 2.

U-value = 0.321 w/m²k

Thermal resistance = 3.111 m²k/w

Material	Thick-(mm)	Conductivity (w/m-k)	Resistance(m²k/w)
Mud-Brick	500	0.17	2.941
Clay-Mortar	20	0.29	2.33

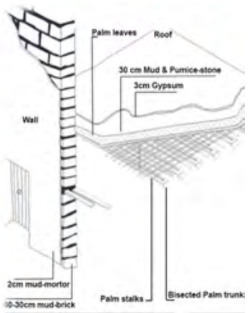

Figure 2. Local construction materials in traditional house

The thickness of the wall varies starting from 75cm on ground level to change at height of 3m to 60cm and then to 50cm at height of 5 to 6m (Al-Zubaidi, 2002; and Allafi, 2012). The size of bricks may slightly vary from building to another as Aalund (1983) stated that brick's size of 40×60mm, 40×50mm and 40×40mm is also found for ground floor, first floor and top floor respectively. The mud bricks are made of a mixture of clay, gypsum and palm date fibre that all mixed up and burred underground for weeks before it is used.

Proposed prototype courtyard house

The proposed design of the courtyard considers various aspects including the climate, social needs and preference, use of land and shared resources, the urban complex and use of renewable energy sources. Figure 3 shows the layout of the ground floor consists of semi-public area for male visitors, semi-private area including the female guest room, kitchen and indoor covered courtyard space as well as semi-shaded carport and garage with a side family entrance. The first floor of the prototype house presents the private family area including inner balcony that overlooking the courtyard as well as summer shed space (loggia) which is used mainly in summer night as part of their tradition and climatic solution. The inner covered courtyard plays an important role in local community life and incorporating this space with elements like balconies, sittings, playground areas and fountain will enhance the quality and performance of entire home.

Figure 3. The proposed design of the courtyard in residential buildings

The courtyard has been moved from the centre as in traditional house to the side position and also from first to the ground floor to integrate certain natural elements includes vegetation and sittings. The courtyard ceiling height has been increased which also offers nice view from first floor balconies and further enhance thermal conditions. Clerestory skylights have been placed in the courtyard roof to enhance daylighting and also promote night ventilation strategy.

Construction materials

Local materials can be efficiently optimised and used in construction as approved to have high thermal performance including the dried-mud bricks, dry limestone sub-soil, and palm tree fibre as an insulation material. DesignBuilder has an editable library which is rich of construction materials and all thermal and physical variables including U-value, thermal and surface resistance, internal heat capacity and reflectance can be calculated. However, there are a number of studies investigated the use of organic materials especially if locally available as an alternative green materials, cheap, sustain longer, reproduced, reused or recycled. With the new technology dried-mud bricks have been developed to enhance its thermal and physical characteristics to achieve great time lag up to 10.5 hours compared to 6.7 hours for the concrete hollow blocks (Kamal, 2011).

In addition, Ghadames Oasis is rich in palm trees and thousands are found around traditional settlements. This type of plant has been under research by many studies testing the viability of its natural organic fibre to be used as an efficient and biodegradable insulation materials (Al-Homoud, 2005; Khiari et al., 2010 and Agoudjil et al., 2011). More recent studies such as Lertwattanaruk and Suntijitto (2015) found that palm oil fibre is a great natural material to be used in industry to replace cement flat sheets to reduce thermal conductivity, optimise heat insulation and decrease its bulk density. Therefore, this study has considered date palm fibre for insulation materials as a green option as Table 1 shows.

Table 1. Wall construction materials in the proposed courtyard

Ext	Material description	Thickness mm	Conductivity W/m deg. C	Density Kg/m^3	Specific heat J(Kg deg. ˚C)
1	Dry limestone blocks	25	1.26	1522	908
2	Sun-dries mud-bricks	150	1.8	1800	712
3	Organic date palm fibres	50	0.08	600	2000
4	Sun-dries mud-bricks	150	1.8	1800	712
5	Gypsum board/mortar	20	0.16	600	1000
In	U-value	**0.211 W/ m^{2}K**			

Courtyard redesign and optimisation

Courtyard configuration

Throughout history the basic plan of a residential courtyard has been developed and modified to meet environmental and cultural aspects (Das, 2006). In this study the design concept and form of the courtyard in traditional housing was investigated and clearly noticed that the form and position of the courtyard plays an important role in modifying the indoor microclimate. Many in literature including (Amer, 2007) and (Heidari, 2010) found that rectangular deep courtyard form performs better for hot or desert climate. In desert climate such as Ghadames the protection of exposed surface of dwelling from intense solar heat and dusty hot winds are key aspects in optimising the courtyard which will have an impact on indoor thermal comfort as recommended by a number of researchers such as (Aldawoud, 2008).

However, there are more than variable have to be taken into account in optimising the environmental performance of inner residential courtyard including orientation, volume, position in relation to interiors. Muhaisen (2006) studied the optimum courtyard proportion (height and ratio) for different climatic zones and found that double ceiling height would determine the best thermal performance in hot arid climate. Hence, the courtyard geometry and proportion and level of exposure to outdoor conditions are considered in this study which will have a significant influence on indoor thermal conditions. However, the study uses a dynamic simulation programme *EnergyPluys* to investigate the performance of existing and optimised courtyard.

Simulation and findings

Traditional house

Simulation is run for typical summer week in July to compare results with actual temperature readings. The average of indoor thermal conditions is slightly higher than the temperature recorded in-situ but remains relatively constant. In Figure 4 comfort temperature (T_{op}) estimated around 34˚C throughout the week inside the living room whilst actual temperature measurements were recorded at 29˚C to 32˚C. This can be interpreted as the microclimate of the old town has been modified by massive green fields and outdoor water surfaces contributed to humidify and drop down ambient air temperature which has not been accounted in the simulation. It is also the technique used to balance thermal indoor conditions during the day and night with aid of less exposure to sun as shown in

Figure 5. The total annual energy use inside the traditional house was found to be 28.87kWh/m^2 as this mainly consumed for lighting and hot domestic water. According to Noguera and Cervera (2012) Passivhaus specified that the annual total energy demand for space requirements should be limited to 20-30kWh/m^2.

Figure 4 Indoor thermal conditions predicted in the central hall of the traditional house

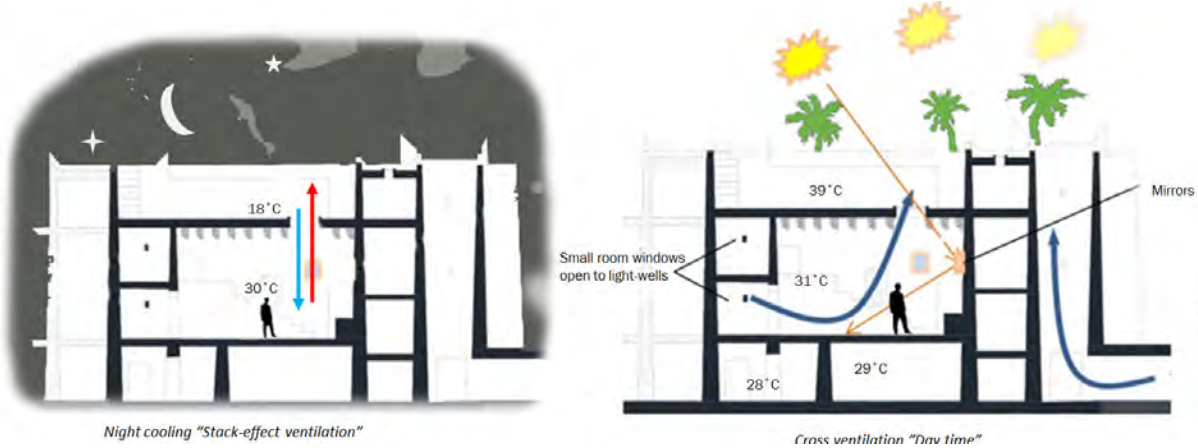

Figure 5 application of natural ventilation inside central courtyard in traditional houses

According to Samaan et al. (2016) EnergyPlus uses one of the best daylighting simulation programmes *Radiance* integrated into CIBSE and LEED calculations. in practice daylight factor of 2% to 5% showed to have a great balance between achieving good daylighting and thermal aspects (CSH, 2010). BREEAM daylight calculations indicate no compliance with minimum standards and the house fail to be adequately lit naturally. However, daylight average inside the central hall has been calculated at 1.21% and indicated poor daylighting distribution.

Table 2. Daylighting inside the central hall in DsesignBuilder

Zone	Block	Floor area (m2)	Min DF (%)	Uniformity ratio (Min / Avg)	Area adequately lit(m2)	Average DF
Living-Room	first floor	17.68	0.07	0.57	5.675	1.21
Total		**17.68**				

Proposed house

A typical summer week in July represents one of the hottest periods in Ghadames where temperatures reach 47˚C during the day and drops down by 26˚C at night. Indoor thermal conditions inside the courtyard were indicated to be far better due to the installation of skylight openings which enhance the night purge ventilation. The temperature was around 28˚C with higher humidity rates than values found in traditional courtyard. In EnergyPlus external openings were set to be open at evening during summer so only that night purge ventilation can take place at the specified time. This showed a significant impact on the heat balance inside the courtyard as can be seen in Figure 6. It indicates that indoor comfort temperature inside the courtyard is relatively constant throughout the typical summer week at 28˚C in natural ventilation mode.

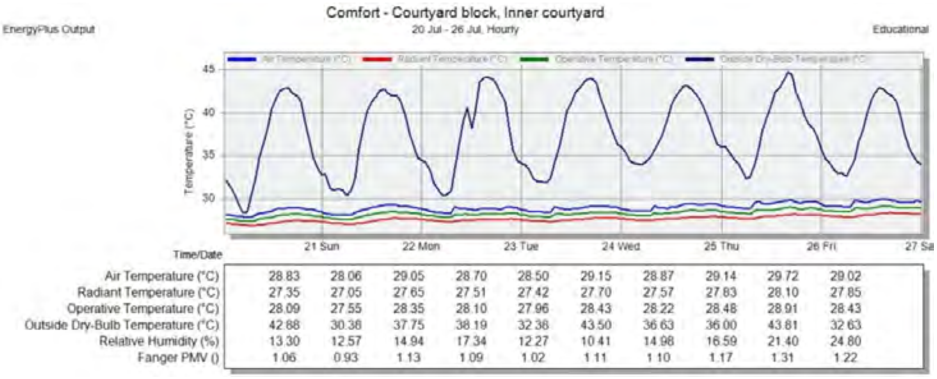

Figure 6. Indoor thermal conditions inside the proposed residential courtyard

However, to achieve the recommended human comfort temperature by ASHRAE 55 which is about 26˚CAC was assumed to be on throughout the summer period from May to October at an average of 8 hours per day. As a result of that a 5.02kWh/m^2 is consumed for space cooling**Error! Reference source not found.**. According to the BREEAM rating the building did not fully achieved daylighting. However, with 15% window-to-wall ratio it is difficult to pass BREEAM credits but fairly can achieve acceptable performance especially in living spaces. In general, the house achieved good thermal performance with relatively good daylighting and the covered courtyard serves as solar room to deliver daylight deeper into interior spaces through skylights as Table 3 shows.

Table 3. Daylighting analysis inside the proposed courtyard

Zone	Block	Floor area (m2)	Min DF (%)	Uniformity ratio (Min / Avg.)	Average DF	Area adequately lit(m2)
Inner balcony	FF	3.960	0.57	0.40	1.4	1.300
Living room	GF	18.880	0.55	0.19	1.2	8.720
Inner courtyard	GF	29.250	0. 70	0.24	2.9	21.320
Total						**31.340**

Conclusion

This study highlighted the significance of both understanding the local architecture and context in designing residential buildings especially in extreme climates such as Sahara Desert. The courtyard in desert architecture has been and still considered to be one of the best options to meet residents' environmental and cultural requirements. Although, traditional architecture is proved to act responsively towards the environment where it stands but may not meet today's living standards. Therefore, this paper aimed to optimise the performance of residential courtyard to enhance the indoor conditions for Ghadames housing. The findings indicated that covered double ceiling height courtyard on the ground floor would have significant impact on enhancing indoor thermal and visual conditions. In addition, it creates a pleasant space for family and integration of natural elements such as water and vegetation would add great impact on indoor conditions. Installing skylights in the courtyard roof have resulted in improving the daylight and night stack ventilation. Local materials readily available found to have high thermal performance and reduce the construction cost which can replace all concrete and some other exported materials.

PLEA 2017 EDINBURGH
Design to Thrive

Vernacular architecture and contemporary production processes, in search of «Relay concepts» between vernacular and contemporary

Linda Bchir[1], Pierre Fernandez[2] and Savitri Jalais[3]

Abstract: Vernacular approach seems to be a realistic and applicable current response to a search for durability and quality in architectural production. My thesis project aims to explore the concept of vernacular architecture and to highlight the potentials of vernacular concepts so as to include them in contemporary architectural design. Our concern consists studying vernacular in architectural design, while focusing on how we can link the vernacular and contemporary projects today. It thus aims to extract concepts from vernacular architecture, that qualify as part of our research called "Relay concepts" that could serve as project tools today in contemporary design. This work will involve defining the consequences of complementarities between vernacular/contemporary, on results obtained in terms of sustainability and quality in architectural production. What is a vernacular architecture? What are the principle generators, concepts and meanings of the fundamental values of vernacular architecture? What are the lessons that we can extract from vernacular in contemporary architectural design? How can we transfer them? Does the term contemporary vernacular architecture viable?

Keywords: Vernacular architecture, contemporary architectural design, Relay concepts, etymology, repossession

Introduction

To be caught between two worlds: that of a thirst for everything that is contemporary and new in terms of design and at the same time admiring the precious examples that exist in the history of architecture. From this situation, our point of departure was born, in the form of latent questions since my first steps at the school of architecture of Sidi Bou Saïd in Tunis, and was further accentuated during my practice in architecture cabinet. Throughout my academic background, I was awakened by many questions concerning vernacular architecture. The debates that exist around this concept permitted me to discover facts which help to understand what vernacular architecture is in general without being able to define it. This term is often unclear, poorly known, its architecture devalued or called minor, folk, primitive, spontaneous, local, anonymous, self-constructed, an architecture without architects, native marginal, traditional or even rural. This profusion of terms arouses confusion and has led to a various theoretical debate on how best to define vernacular architecture. Later, during my professional internships and my two years of practice in architecture, I realized that in practice these valuable examples of architecture instead of being acquired and used as guides, often, unfortunately, are reduced to formal elements functioning only on the surface, as decoration of buildings or ephemeral acts. Today, I want to give coherence and meaning to my career and find a new way of apprehending, understanding and conceiving architecture by linking the vernacular and the project.

The opportunity to rethink how to apprehend and conceive architecture

Vernacular architecture has long been devalued and underestimated, although 95% of the built environment in today's world, according to the research of architect and urban planner Amos Rappoport (Rapoport, 1972), can be considered as being vernacular. He estimates that only 5% of the buildings in the world are the result of the work of architects. However, it is an architecture that we do not enough speak about, if ever, because it is wrongly considered as a "minor architecture compared to the architecture of architects" (Guindani and Doepper, 1990).

Today, environmental issues and technological advances give another dimension to vernacular architecture and local resources. Many authors speak of a need to define and raise awareness of this architecture that has long been neglected. In this perspective, our theses research aims at highlighting the lessons we can learn from vernacular language in contemporary architectural design, while focusing our reflection on how we can link the vernacular and the project today. It aims to extract concepts from vernacular architecture, that qualify as part of our research called "Relay concepts", that could serve as project tools today in contemporary design. What is vernacular architecture? What are the generators principles, concepts and meanings of the fundamental values of vernacular architecture? What are the lessons that can be extracted from vernacular in contemporary architectural design? What concepts of vernacular architecture do contemporary architects reinterpret and reintroduce into their projects? How can they be transposed? Are vernacular and contemporary antinomic? Does the term contemporary vernacular architecture viable?

These are the fundamental questions which this thesis attempts to answer.

Knowledge transfer strategies, from local to global, from the most specific to the most general

Vernacular architecture is strongly influenced by the local context, cultural patterns and the impact of physical environments; it refers to the specificities of a population and a territory. Enforcement remains variable from one country to another, and its design is in permanent evolution, adaptable to the constraints of specific regions. Thus, even though vernacular architecture is a local architecture, could it have universal validity criteria (constants)?
This last seem to be in the form of proven architectural concepts of vernacular architecture, generalizable, adaptable and transposable to other contemporary situations. We thus formulate the hypothesis that the approach of identifying universal validity criteria (constants) in vernacular architecture, could help us develop a research approach for contemporary architecture based on the proven concepts of vernacular architecture, as well as to constitute a corpus of knowledge and contribute to a reconciliation between the vernacular and contemporary. The vernacular approach seems to be a realistic and applicable response to a search for durability and quality in architectural production. We thus arrive at the hypothesis that vernacular architecture will only be a source of contemporary inspiration, inasmuch as the architect is able to grasp the deeper meaning of vernacular architecture. This may also have an impact on the pedagogical approaches of

higher education, which must be accompanied by an emphasis on the lessons we can learn from the vernacular in contemporary architectural design.

Method relating theory and practice

The methodology we propose is based on the combination of two approaches; it will be built step by step by relying on different corpuses:

Theoretical corpus of epistemological and lexical order

My theoretical approach proposes to explore the notion of the vernacular through its etymology, thus understanding how the vernacular word was introduced into the history of architecture and history of the French language.

A comparative study of the use of words close to vernacular, such as: popular, common, ordinary, traditional, native, spontaneous, in the theoretical and critical texts of architecture is essential to see whether these words refer to same objects. The objective would be to be able to locate the vernacular in relation to these terms that are close to it. "All these words as alone and together can reveal an architectural image, the nuances that lie between them require us to make an investigation to better approximate the vernacular concept" (Mercer, 1979). We therefore wish to take advantage of this study to clarify our vision of vernacular which is quite vague and position ourselves in the great theoretical debate about its definition.

Our bibliographic research will be deepened within the framework of the thesis and will focus on the most important critical and theoretical studies of vernacular architecture such as:

- The work of Frédéric Aubry (Aubry, 1999) at the Federal Institute of Technology in Lausanne, who was able to create with his students a "collection" of more than 680 models 1/20 scale that takes up vernacular works. These mockups have a pedagogical purpose and serve as predefined templates to assist students during their process of transposing and adapting old techniques to contemporary situations.

- The research of Pierre Frey (Frey, 2010), which represents a starting point in our reflection. They give back a new dimension to vernacular architecture. These lead to an exhibition of the work of Frédéric Aubry (Aubry, 1999) and then to the publication of the book "Learning from vernacular" which questions the meaning and relevance of a vernacular architecture today.

- The research of Pierre Frey (Frey, 2010), which represents a starting point in our reflection. They give back a new dimension to vernacular architecture. These lead to an exhibition of the work of Frédéric Aubry (Aubry, 1999) and then to the publication of the book "Learning from vernacular" which questions the meaning and relevance of a vernacular architecture today.

- Welsh School of Architecture: The open-air museum at St Fagan serves as a laboratory for first year students who have the opportunity to observe and analyze the collection of Welsh reconstructed buildings on site for a week. A new approach to teaching is proposed in this school of Welsh architecture, the latter is based on the use of vernacular architecture as a model for the environmental design of buildings.

- The Atlas of vernacular architecture of the world (Vellinga et al, 2007) which brings together an impressive stock of vernacular works studied, listed and classified according to specific criteria. This encyclopedia is the first to show the remarkable diversity of buildings built and inhabited by people of more than a thousand cultures.

On the other hand, our research will also cover Internet sites of organizations dedicated to the study and enhancement of vernacular architecture such as ICOMOS (International Council of Monuments and Sites), CIAV (International Scientific Committee On the vernacular architecture), CERAV (National Center for Textual and Lexical Resources).

A pragmatic corpus based on analysis of concrete projects

My field work will be done with a rigorous and referential methodology and will follow the following approach and logic:

- An architectonic observation followed by analysis to recognize constant adaptations, of a vernacular architecture.
- These adaptations will be analyzed as a response to the socio-cultural and environmental environments, in order to understand the path of a vernacular architecture that depends closely on the site, the landscape, the climate and the materials.
- To identify and analyze architectural concepts from the vernacular world, to sort them from the most local to the most global, from the most specific to the most general, then to combine them, to synthesize them, and finally to find constants that are conceptual and transposable to others situations.
- Identify and analyze contemporary architectural projects bearing these previously studied, synthesized concepts, coming from the vernacular world and implemented in contemporary architecture (In order to explore the process through which, some contemporary architects have looked at the vernacular architecture).
- Understand how, according to what logic and how they were transposed?
- Define the consequences of complementarily between vernacular/contemporary, on the results obtained in terms of sustainability and quality in architectural production.

All this investigation will be done using the techniques of pedagogical investigations namely:

- Site visit which allows a direct visual perception of the built environment.
- Methods of surveying to update the material support of this research (topographic maps and plans at different scales and at different times).
- Comparative study: My case studies with countries forerunners of the contemporary reinterpretation of ancestral constructive tradition.
- Reading, sorting, analyzing, interpreting and synthesizing of various data collected.

Towards an intercultural ground, case study of vernacular and contemporary projects in the South west of France and in the south of Tunisia

I would like to point out that I will enjoy my Tunisian-French cultural background in the selection of Pragmatic Case Studies. It would be more judicious to choose examples; rich in teachings, from diverse origins (located in different parts of the continent, with a rather different historical and cultural development), bearing one or more vernacular concepts preferably, easily illustrated with a picture or drawing. In our choice of case studies we tend to favor those from the UNESCO World Heritage database, and those that are recognized as representative of the vernacular architecture.

South west of France: The vernacular architecture of the Landes of Gascony

The territory of our study is 'the Landes of Gascony' (Figure 1), limited to the north with the Bordeaux vineyards, south of Chalosse, in the east by the Garonne and to the west by the Atlantic Coast, Situated in the Aquitaine region (South West of France), geographically located in the Midi Atlantic.

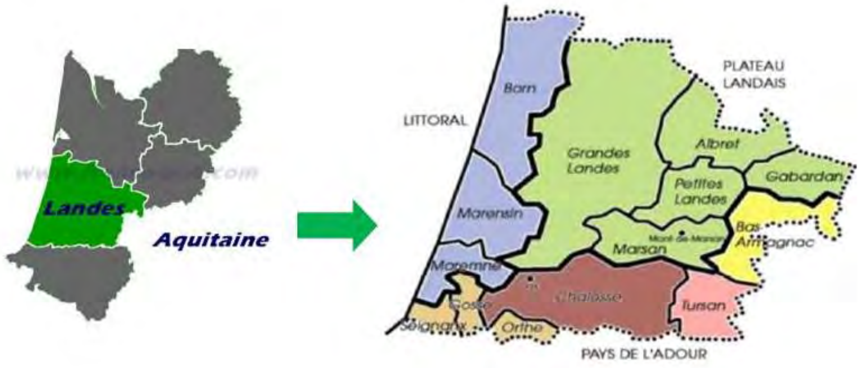

Figure 1. Territory of our study: the Landes of Gascony.

The Landes vernacular house (Figure 2):

Is a very illustrative example of vernacular architecture, rich in studies, for all that theoretically we can read on vernacular and bioclimatic architecture, we see it and we live through its vernacular built environment. After my beginnings of research, my site visits and my architectural observation I think that the Landes constitutes a wealth of didactic because of its buildings built, which is a traditional urban ensemble that retains the marks of an ancestral know-how in construction and architecture.

Figure 2. The Landes vernacular house.

Traditional habitat of landes has demonstrated its quality in terms of constituents of landscape, respect for the environment, adaptation to climate, use of local resources and know-how. According to "CAUE" of Landes : «The Landes house is an example of the persistence of an architectural type that denotes the adaptation of its visible characteristics to its geo-climatic environment» […] «An architectural and patrimonial identity in the Landes, very nuanced and stratified in time, which invites us to rethink contemporary modes of production".

For these reasons this type of vernacular architecture will bring to our study the basic elements which will also allow the analysis of other examples of vernacular architecture throughout the world.

In figure 3, we illustrate an example of project which deploys a contemporary architecture that draws references to the vernacular Landes context.

Figure 3. Cocon landais - WHY Architecture: An architectural firm that intervenes in subdivisions by reinterpreting the vernacular architecture of the Landes houses.

South of Tunisia: The island of Djerba

Djerba (Figure 4) is an island of 514 km^2 (25 kilometers by 20 and 150 kilometers of coast) located in the southeast of Tunisia. It is the largest coastal island in North Africa. The Tunisian government has proposed Djerba for a future classification on the UNESCO World Heritage list.

Figure 4. Territory of our study: the island of Djerba

Vernacular architecture of Djerba:

It is a very illustrative example of vernacular architecture, rich in studies (Figure 5). By contemplating the vernacular buildings in Djerba, we felt that they are in symbiosis with the environment and that their mass melts in nature; there is a perfect harmony between the building and the natural environment. This is due to the small scale of the buildings; there is neither ornamentation nor openings (due to the discretion of Djerbian (culture and religion) on one side and its small size on the other hand), their color (The omnipresence of white) and the materials used that come precisely from nature.

Figure 5. Model which illustrate the vernacular house of Djerba, derived from the work of Frédéric Aubry (Aubry, 1999) at the university or federal institute of technology in Lausanne (Learning from vernacular).

Many contemporary architects (Figure 6) have been strongly influenced by the vernacular architecture of Djerba and interpreted in a contemporary way to reach a compromise between vernacular and contemporary.

Figure 6. Ba-studio: Samia ben-Abdallah architect, elected as ambassador of the ecological architecture in Tunisia.

EXPECTED RESULTS: From strategy to implementation

The ultimate goal at the theoretical level, will be to present a complete investigation of vernacular architecture in order to contribute to the progression of its definition and to try to clarify the confusion that prevails, To achieve this, we thought of the idea of elaborating a landmark consisting of two axes: a historical axis (from oldest to newest) and another spatial one (from local to generic). The objective would be to be able to classify these various lexical elements close to the vernacular and to position them according to this landmark. It will be a working and discussion tool which, in our opinion, should enable us to situate the vernacular in relation to these terms which are close to it.

The ultimate goal on the pragmatic level, therefore, will be to build a corpus of knowledge, which will take the form of a repertoire of «Relay concepts» between vernacular architecture and contemporary architecture. It is a matter of bringing these architectural concepts together in a data bank enriched with new knowledge in the field. It would offer a typology of architectural concepts previously studied, synthesized and allowing a fast and efficient reading for eventual appropriation. On the other hand, there is already an initiative led by Pierre Fernandez (my thesis supervisor) in the direction of my research work under the name of "Thinking the relationship between architectural quality and environmental quality" 'materialized by creating a directory relay concepts of architecture and environment.

We wish to clarify that this is certainly not developing pre-established recipes. But rather to propose a methodological approach that can serve as references for integrating vernacular concepts in contemporary architectural design.

Revitalizing traditional knowledge: The sustainability of the vernacular house in the northeast of Mendoza (Argentina)

Matías Esteves[1]

[1] Instituto de Ciencias Humanas, Sociales y Ambientales, Consejo Nacional de Investigaciones Científicas y Técnicas, Mendoza, Argentina, mesteves@mendoza-conicet.gob.ar

Abstract: This research explains the relationship between sustainability, traditional knowledge and thermal comfort in vernacular housing in the non-irrigated drylands of northeastern in the province of Mendoza, Argentina. The analysis of rural vernacular housing is presented as an opportunity context to deepen in the traditional knowledge of the inhabitants regarding the bioclimatic strategies that unfold in order to reach comfort in territories characterized by limited availability of natural resources, with extreme climatic conditions and no infrastructure. The objective is the description and characterization of the bioclimatic strategies currently developed focused on the materialization and the operation of the house. According to the fieldwork and the interviews carried out it is observed the use of natural materials predominates, although industrialized materials are incorporated. Also, the use of the shadow is a key in the strategies to reach comfort. The results show that the strategies adopted by the inhabitants are the best way to acquire comfort with the resources they have available. This derives from empiricism and from the traditional knowledge they have inherited about materials, constructive forms and knowledge of the climate. For this reason, rural vernacular housing remains as a sustainable architecture.

Keywords: Vernacular house, traditional knowledge, bioclimatic strategies, sustainability

Introduction

More than half of the energy consumed on the planet is linked to the construction, both in materials production and construction, as well as in the maintenance and the operation of buildings. For this reason, the construction of the habitat represents one of the most significant physical impacts on the natural ecosystem (Sanchez, 2005). Faced with this situation vernacular architecture is a target again, due to the fact that in the international literature, several authors agree on pointing it as a model of sustainable architecture, although it is mainly linked to a pre-industrial era. Anyhow it remains in force, even though it presents adaptations to adjust its operation to the new territorial challenges (Esteves, 2016).

Vernacular architecture is deployed as a social and cultural complex system. It is originated from the culture-nature duality and it directly reflects the ways of living (Tilleria, 2010) in tune with the physical space where it is located (Coch, 1998). The International Council on Monuments and Sites (ICOMOS), in its Charter on the Built Vernacular Heritage, defines this architecture as *"the fundamental expression of the culture of a community, of its relationship with its territory and, at the same time, the expression of the world's cultural diversity"* (ICOMOS, 1999:1). In this Charter its characteristics are summarized as follows: 1.

A manner of building shared by the community; 2. A recognizable local or regional character responsive to the environment; 3. Coherence of style, form and appearance, or the use of traditionally established building types; 4. Traditional expertise in design and construction which is transmitted informally; 5. An effective response to functional, social and environmental constraints; 6. The effective application of traditional construction systems and crafts (ICOMOS, 1999:1)

All these characteristics link it directly with sustainability as it recognizes the local climate, the materials used, the users and the traditional knowledge transmitted informally among generations. The traditional knowledge involves the accumulation of knowledge, techniques and tools within a community (UNCCD, 2005) that shows from the empiric a certain understanding about the characteristics of the natural ecosystem. Although in several texts the traditional techniques and knowledge are associated with a cultural backwardness, many organizations and authors (UNCCD, 2005; Rabey, 2004; Esteves, 2016) have emphasized and demonstrated the importance that they present for sustainable development since they involve an approach at local level where the inner characteristics of a specific territory are rescued.

Characterization of the area of study

Topography

The area of study is a broad arid plain that is structured by dunes up to 20m height, alternating with indents and sinkholes. This area has been affected by strong processes of desertification since the middle of the 20^{th} century. This has involved the lack of surface water and the disappearance of forest areas (Roig et al, 1991).

Climate

Desert-semi-desert type, where the recorded temperatures present an absolute maximum of 42ºC in summer and an absolute minimum up to -10ºC in winter, with large daily and annual thermal amplitudes. The rainfall regime is mainly characterized by the presence of summer convective storms, although annually are recorded between 50mm and 150mm of rain, depending on the area. This added to the lack of surface water sources, the relative humidity ranges between 48% and 68% (Estrella et al, 1979).

Population and productive activities

The productive activities are small-scale and family-type. They are mainly based on the goat rearing and in the manufacture of handicrafts. In some cases, the products that are obtained are destined to the extra-local market and in another cases they retract on the family for self-consumption (Torres, 2010). The population is composed of several families that are located in the territory in two ways: in small settlements located on the banks of the Mendoza River in populations that do not exceed 40 houses, or located in dispersed houses into the interior of the territory around old lacustrine complexes, dry nowadays. The present work focuses on the study of these dispersed houses.

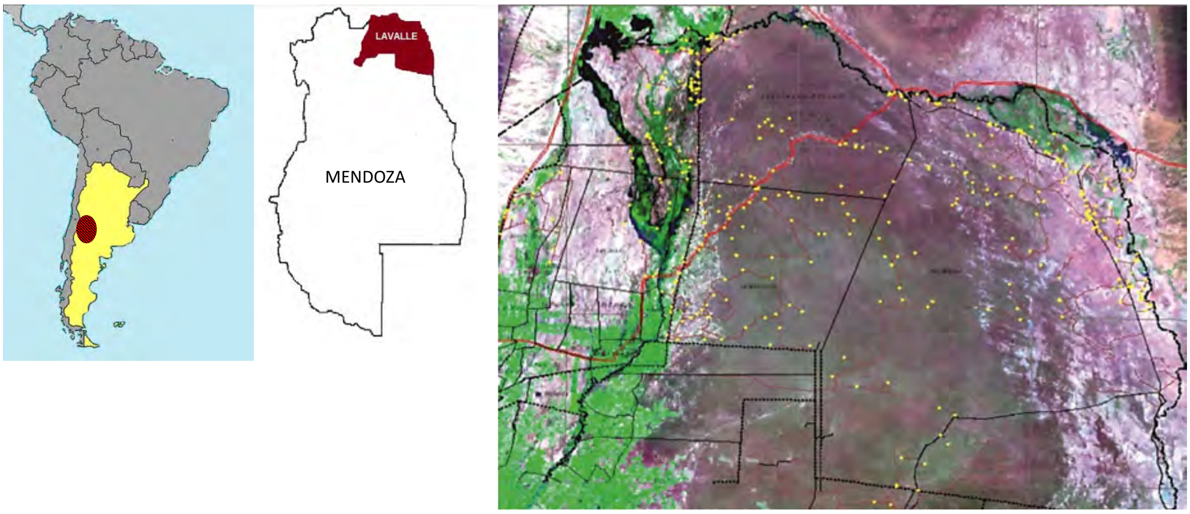

FIGURE 1. Geographical location of the area of study. Each yellow dot indicates the location of a dispersed dwelling. The dispersion of them is linked to the arid characteristics of the territory. Source: SIG DESERT - LaDyOT / IADIZA.

Methodology

Fifteen dwellings that are characterized by their isolation and dispersion in the territory and their direct dependence on nature were analyzed. They lack of basic infrastructure and services to obtain artificial comfort conditions.

With the purpose of characterizing the bioclimatic strategies used to reach comfort and to investigate the existing traditional knowledge related to habitat construction, qualitative methods have been used, such as participant observation and in-depth interviews.

Description of the houses

These dwellings are characterized by two juxtaposed spaces: the interior space and the intermediate space.

The interior space is configured as a sequence of adjoining rooms without corridors or spaces destined exclusively to the circulation (Pastor, 2005). This are the rooms used at night for sleeping and, to a lesser extent, for cooking and dining. The use of mud earth stands out in these rooms: Adobe walls -varying thickness from 0.25m to 0.30m- or quincha –mud and cane mixture with a thickness of 0.10m to 0.15m-) and in few sectors, it is noticed the use of bricks (thickness 0.20m). In all cases, the joints between masonry are made with mud mortar. In all homes, the ceiling is flat roof with minimal grade and its structure is materialized with poplar logs. Over this, it is placed a cane grate and finally a blend of mud. On the outside it is common to find an expanded polyethylene sheet to reduce the action of rain on the mud roof.

The intermediate space is attached to the interior space (figure 2), mainly on its north side. In this space most of the daily activities are performed during the day, both in winter and in summer. It is materialized by wooden pillars made with algarrobo (*Prosopis flexuosa*) and beams of the same material, although it is usually combined with poplar logs. The roof is materialized with cane making a distribution mesh, a sheet of polypropylene and on this, a blend of mud. To a lesser extent, light roofs are resolved with industrial materials such as synthetic mesh or corrugated zinc sheet.

FIGURE 2. Photographs of dwellings: Volumes and materials used and the natural context of the site. The interior and intermediate spaces are appreciated (Source: Author)

Self-construction is frequent for the building and extension of the house as well as for the maintenance of housing, where the whole family participates with the help of neighbors or relatives. This situation inevitably involves traditional knowledge and the knowledge transfer among generations.

Regarding how they obtain the materials used in the construction of the house, all the interviewees agreed to indicate that they use the resources available in the natural environment because of their low cost; even in the case of adobes or quincha they are manufactured by them. Interviews data indicate that the inhabitants show certain knowledge of the advantages, disadvantages and characteristics of each material, in terms of construction techniques, quality, time and frequency of maintenance and thermal behaviour. In the same interviews it is also shown that they prefer the use of natural materials for two main reasons identified in the fieldwork: On the one hand, because of the continuous use in time of this materials and the knowledge transfer from generation to generation results in the identification of the social group. On the other hand, for the trial and error process the inhabitants have verified the thermal efficiency of these materials to the external climate, even comparing them to industrial materials.

The most used materials are those made with mud such as adobe walls -width ranging from 0.25m to 0.30m- with a density of 1600kg/m^3 and thermal conductance of 0.70W/m^2°C and the quincha wall (Cuitiño et al, 2014) considering a width of 0.10m, density of 1450kg/m^3 and thermal conductance of 1.34 W/m^2°C. The canes used in the ceilings have a thermal conductance equivalent to an expanded polystyrene sheet of 7mm thick (Cuitiño et al, 2005). The blend of mud used in the covers (0.10m of mud plus a row of cane) has a density of 1450 kg/m^3 and thermal conductance of 1.34W/m^2°C. Because of these characteristics, they are more insulating than industrialized materials, where the brick wall (thickness of 0.20m) has a density of 1800kg/m^3 and a thermal conductance of 2.12W/m^2°C, while the corrugated zinc sheet has a density of 2700 kg/m^3 and thermal conductance of 4.47 W/m^2°C). It also affects the morphology of housing, as its compact form, helps to obtain greater thermal inertia against the variations of the external climate.

In order to inquire the bioclimatic strategies developed by the inhabitants to achieve comfort, it was used in the first moment the diagram of Givoni adjusted by Milne et al (2009) with the aim of analyzing the strategies that should be considered in the area, to later corroborate in the fieldwork its use. It has been chosen to place in the graph of Figure 4 the critical months (January and July) and an intermediate month (April). According to the diagram, in winter the strategies to reach comfort would be solved mainly with passive solar heating and only a few days and cold nights auxiliary heating, besides the use of thermal mass, already exposed in the previous paragraph. In summer it is indicated the use of natural or artificial ventilation, thermal mass and night cooling.

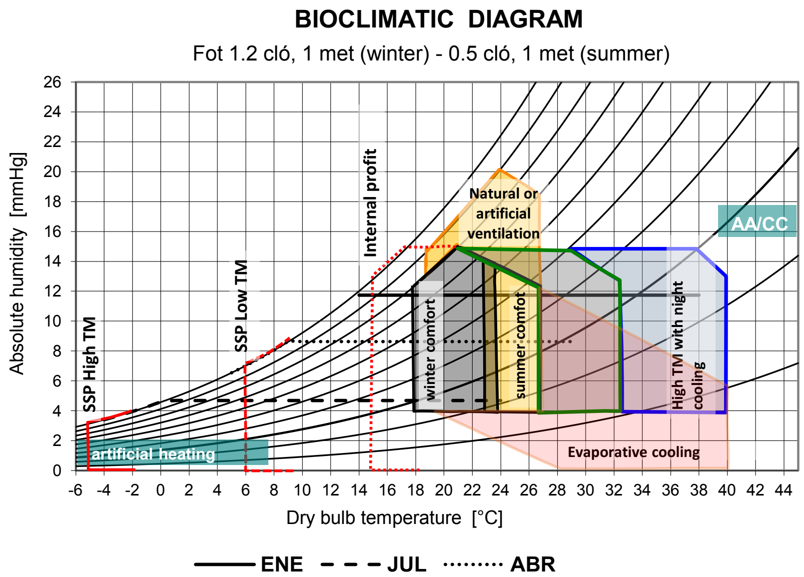

FIGURE 3. Givoni diagram with bioclimatic strategies to achieve comfort according to temperature, humidity and air characteristics.

In tune with the diagram, in the fieldwork they are noted the strategies the inhabitants deploy to achieve thermal comfort. During the summer season, the inhabitants sprinkle water in the intermediate spaces and in the interiors in order to generate evaporative cooling and ventilation to reach a microclimate. This practice is already commented by the artist Roig Matons in his trips to the site since 1930, as a local practice to reduce temperatures (Roig et al, 1999), which indicates the knowledge inherited from past generations.

It is also noteworthy that there prevail small windows, which purpose is to avoid the direct incidence of solar radiation and to prevent the exchange of temperatures between the indoors and exterior. Also, windows are found in all the orientations for the use of cross ventilation for night cooling; this aspect is reinforced in the morphology of the house because they are adjoining rooms without corridors or spaces destined exclusively to the circulation.

The use of the intermediate space is also an important element as this space acts as a mediator, as a nexus between the interior space and the external climate. In the intermediate space most of the daily activities are carried out, taking advantage of the sun setting in winter but blocking the radiation in summer, generating a shadow space (Figure 4).

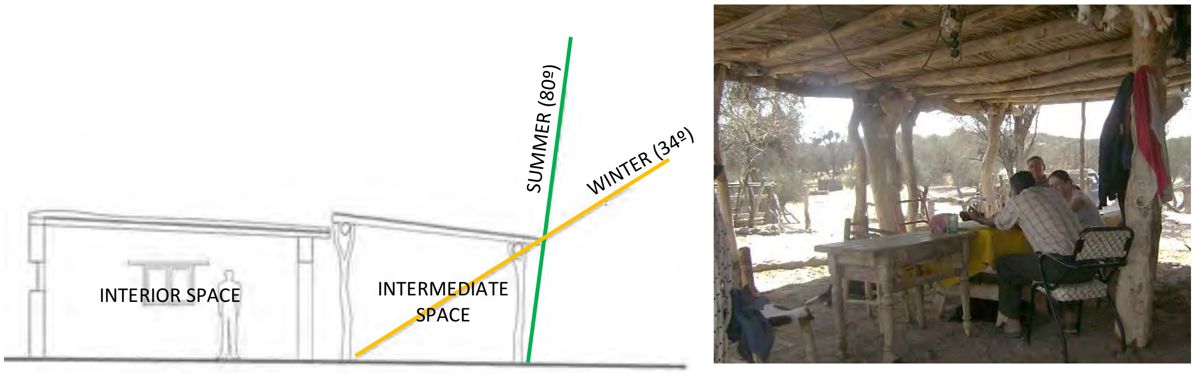

FIGURE 4. Sunlight. Schematic section showing the angle of solar incidence in winter (June) and summer (December) at midday and a photograph of the intermediate space (Source: LaDyOT, IADIZA).

According to the analysis of the comfort temperature throughout the year, the shade is a key strategy to contribute to the comfort. Figure 5 shows the necessity and type of shade (temporary or permanent) according to the solar trajectories of the place and these are based on the time of year and time of day.

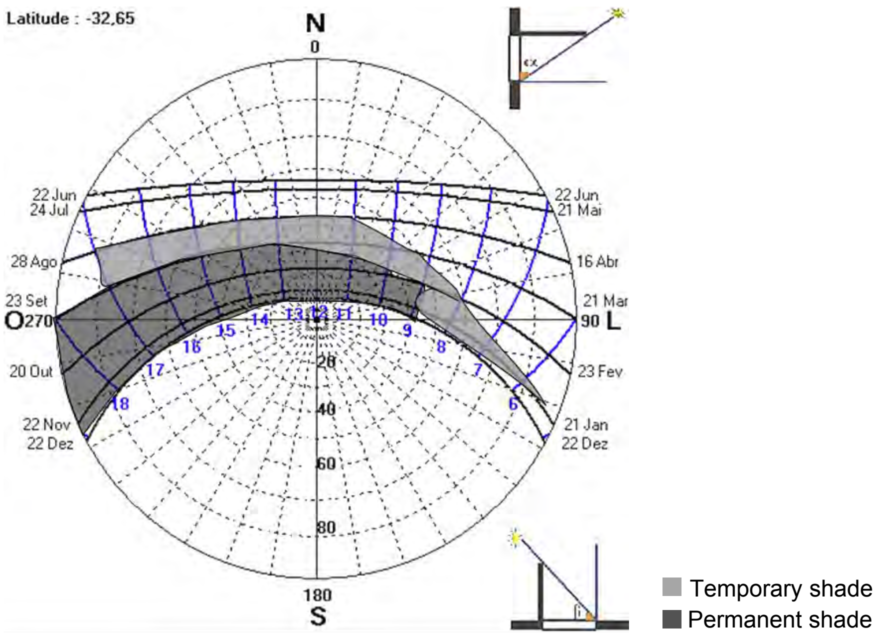

FIGURE 5. Type and necessity for shade during the year.

To obtain temporary shade, exterior elements are used in windows made of cane, wood and synthetic mesh (Figure 6). In respect of permanent shade, it is registered the use of horizontal eaves and the intermediate space that is located mainly towards the north. These elements are made of natural and industrialized materials, which vary according to the ease of assembly, orientation of the window, costs and availability of natural materials on site.

FIGURE 6. Elements used to protect the windows and intermediate spaces made with different materials.

It is clear that the strategies adopted by the inhabitants result in the best way of acquiring comfort with the resources - social, economic and ecological - that they have. In addition, the intangible aspects involve the traditional knowledge produced by experience through trial and error process to achieve the best way to link with the natural ecosystem. For this reason, the sustainability of the vernacular housing in the northeast of Mendoza not only implies the approach of materials and constructive techniques, but also the practices and knowledge that influence its functioning.

Conclusion

In the vernacular housing of northeastern Mendoza in the Center-West of Argentina, various passive strategies are used to achieve comfort that are directly linked to the traditional knowledge inherited from generations that involve accurate knowledge regarding the climate.

The adoption of industrialized materials in the materialization of housing shows the capacity of resilience of the population, although they prefer the use of natural materials, as they recognize the advantages they have regarding thermal insulation. It is observed that the changes are in terms of materials and not of knowledge to achieve comfort. In this sense, the knowledge regarding the need for shade, ventilation and thermal mass has not disappeared and remains in force. For this reason, it coincides with UNESCO when it argues that traditional knowledge is constantly recreated in the adoption of new materials or in the replacement of materials that are no longer available in the environment (UNESCO, 2003). This helps to keep sustainability "alive" since its permanent readjustment.

It has been tried to show both the traditional knowledge and the bioclimatic strategies as allies of the local sustainability and that they derive of the accurate knowledge of the inhabitants regarding to the characteristics of the natural ecosystem. The vernacular architecture that sometimes can be classified as simple encloses precisely in its simplicity a deep knowledge of the natural and cultural environment where it is located and therefore implies the revision of sustainable strategies or forms that it deploys to revaluate it in the current production of architecture.

Building environment assessment methods and social studies of rural villages in Yunnan and urban development in Chongqing City, Southwest China

Yun Gao[1], Adrian Pitts[1], Lili Dong[2], Guo Chen[1]

[1] Department of Architecture and 3D Design, University of Huddersfield, Huddersfield, UK, email for correspondence: y.gao@hud.ac.uk
[2] Faculty of Architecture and Planning, Chongqing Jiaotong University, Chongqing, China, email for correspondence: 12798062@qq.com

Abstract: Recent urbanization processes and corresponding government policies in China have highlighted the need for much greater understanding of sustainable development and the requirements for sustainability in settings that are very different in rural and urban regions. This paper examines practice and knowledge linked to typical vernacular houses constructed since 1950 in Yunnan Province and regional buildings in Chongqing City in Southwest China. Both areas have played crucial roles in contributing to regional architectural design since the beginning of the 20th Century because of the diversity arising from numerous ethnic groups and various climate types and topography features in the region. The study explores how academic and end-user knowledge accumulated and developed, and how this has revealed social, cultural and political influences on how designers and consumers were motivated towards sustainable design over the same time period. It is argued that locally shared knowledge bases should be considered important for informing governmental policies, planning strategy and consumers' preferences, as well as influencing actions and social acceptance in relation to sustainable development. Furthermore, sustainable design should not be regarded as a contemporary new idea, but one that has its roots in the historical changes in built environment design and practice.

Keywords: Rural and urban development, regional architecture, local knowledge, sustainable development

Introduction

The concept of sustainable building design has been widely used in different countries and regions, and much research has been done to examine the suitability of international and national sustainable building assessment criteria for use in particular regions and societies. McCool and Stankey (2004) stress that the concept of sustainability is socially and culturally related, however, many studies point out that local cultural and social dimensions of sustainability have often been excluded in the assessment (Brand and Karvonen, 2007; Hueting & Reijnders, 2004; Liao, He, 2015). Zhang (2015) finds that the existing studies mainly focus on the environmental aspect of green building while other dimensions of sustainability, especially social sustainability, is largely overlooked. Zhao et al. (2015) analyzes the social problems of green buildings from the humanistic needs to social acceptance and argues that social processes with consumer engagement and participation needs to be considered in design, construction and operation processes to improve users' happiness and productivity. However the consumers are not always readily motivated or may even prefer expensive technological "gadgets" for reducing energy use. To really reflect preference and influenced actions, social acceptance should be analyzed to fully gauge interest and perspective of the people.

This investigation seeks to determine various attempts being made to engage in sustainable design and construction ys in Southwest China. It is argued that the knowledge accumulated and developed over historical periods have revealed social, cultural and political information on how designers and consumers were motivated for sustainable design in the past. Scoones suggests that the importance of knowledge bases of sustainable design and construction need to be considered as asset distinctive from the other five aspects of 'capital': physical, financial, human, social and natural. Shared local knowledge capital can dynamically and continually evolve within communities and support the livelihood and wellbeing of people (Scoones 1998). This study investigates locally shared knowledge that developed in both rural areas and urban cities in China. Although reflected in different ways, they have had significant impacts on decisions for building regulations and planning strategies, and have informed user and consumer preferences for sustainable ways of life. There has been a continuity of thought and action in architecture of what is termed "sustainable design" today, both in rural and in urban development in China since the 1950s.In particular, this paper examines changes that have occurred since the 1950s in practice and knowledge linked to typical vernacular houses in Yunnan Province and in regional buildings in Chongqing City, Southwest China.

The analysis of regional buildings commenced with anthropological studies of ethnic group houses in Yunnan and cultural studies related to indigenous buildings in Chongqing which have occurred since the beginning of the 20th Century. The regional architectural 'knowledge' had developed and been re-interpreted from architectural theories derived from Russia in the 1950s and 1960s and which were then influenced by theories from the West from the 1980s, including the latest concept and theories of "sustainable architecture". The project entails both analytical and interpretive methods of textual research and is also based on materials collected in field studies in Yunnan province and Chongqing city.

The study seeks to explore how the rich and diverse construction traditions in Yunnan and Chongqing reveal their historical roots that are radically different from how the concepts of sustainability and environmental design developed elsewhere. In particular it considers how the concept of the sustainable built environment, particular in its cultural and political dimensions, has been associated with the heritage of vernacular buildings in rural and regional buildings in urban areas. It also considers how local shared knowledge and knowledge from academic study have been considered as an asset directing local government policies and planning strategies. On the other hand, these studies also suggest that new market developments have brought new knowledge to professionals and users. Incentive policies and mandatory regulations are needed to achieve overall sustainable development in the context of China's combined central planning and modernised market economy. To apply the different theories and sustainable assessment methods successfully in the local context, this paper argues that the appropriate sustainable methods and assessment indicators to be used, should take account of local knowledge bases that have accumulated in the past.

Rural development in Yunnan

Yunnan is a diverse part of China with representation in the population of 25 out of the 55 officially recognised ethnic groups in China. Villagers' traditional knowledge of designing and building their own houses in the context of special natural environments formed local shared knowledge capital. The earliest systematic studies of vernacular houses of villages and rural settlements inhabited by these groups were carried out in the 1950s and 1960s. From 1950 to 1963, in order to understand and carry out the classification of the ethnic groups in Yunnan, two stages of identification and investigation of ethnic villages were carried out. More than 1,700 anthropologists, ethnologists, sociologists, architects and artists visited villages to investigate and provide 'scientific' reports about the ethnic group life (Ma, 1999). This was the first time that rural settlements were studied with scientific objectivity; a process that had not been evidenced in previous examinations. The survey focused on the use of traditional materials, construction techniques and characteristics of different houses of ethnic groups, as well as how the vernacular houses had evolved to suit the natural environment, the economic conditions and ethnic group habits. The ‘aesthetic’ aspects of vernacular houses and habitat settlements, represented by a large number of artistic works, were also introduced to the general public in the country. This partly contributed to creation of Yunnan as a thriving tourist attraction after the 1990s.

Following field studies carried out by researchers in the 1950s, four classifications of houses with different materials and technologies were identified in Yunnan. These were initially considered as representations for different stages of housing development over an extended period of history; in chronological order: Ganlan houses (stilt houses raised from ground), Tuzhang houses with adobe or earthen walls, Jinggan houses with overlapping logs serving both as walls and load bearing structure, and Courtyard houses(Figures 1 and 2).

Figure 1. Stilt house and courtyard house. Photos by Yun Gao

Figure 2. Tuzhang and Jinggan houses. Photos by Yun Gao and Adrian Pitts.

The study of vernacular houses in the place where they were found was called “studying in a live museum” with examples showing “primitive” houses and more developed ones co-existing at the same time. The purpose of surveying ethnic groups’ houses was to understand better the cultural heritage of vernacular houses and their use in contemporary design in order to inherit and develop the tradition in contemporary architectural design (EGYVH, 1986). The studies also defined the classification of ethnic groups and their villages and houses by their links with the ethnic group history, religions, and habits. This academic knowledge about ethnic groups and their built environment directed the planning strategies afterwards.

Following the economic growth in the 1980s, unlike villages in coastal areas that developed small industries, the majority of villages in Yunnan had their primary income from agriculture. China's fiscal systems were a combination of subsidies and taxes. Financial support from the local government and the planning of tourist villages were crucial issues to support development. Local policies and plans inherited the classification methods developed from anthropological studies in the 1950s and 1960s, but with a shift of understanding. Rather than emphasising different forms of houses as representatives of different historical stages, new planning considers all traditional forms of houses having equal cultural values that needed to be protected (Gao, Pitts, Gao, 2014). Surveys of villages for planning strategies after the 1990s used four survey categories for reference as follows:

Table 1: Categories of Village Houses

Categories	Criteria	Policy guidance
First category	Well-preserved traditional houses that have embodied historical and cultural values	Protect
Second category	Traditional houses that are in a derelict state and require renovation	Protect, renovate
Third category	Those using a mixture of traditional and contemporary styles; many of which may have employed contemporary technology and materials but try to imitate the traditional styles at the same time	Recommend to modify
Fourth category	Houses that have used contemporary/modern materials and technologies and had no consideration for traditional forms	Recommend to rebuild

Villages generally have more houses in the third and fourth categories than the first two, because they were influenced by widespread development of urbanization processes, and there was a disproportionate rate of replacement of vernacular style houses by new concrete and brick houses. The majority of villagers adapted to market liberalisation and improved transportation infrastructure by giving up the wooden houses and built with new materials such as bricks and concrete. The traditional knowledge of timber houses was considered less useful, however, farmers in the studied villages still help each other to build and increasingly improve their knowledge of new materials and technologies. The cooperation in housing construction maintained the value of culture and a villager's sense of belonging over long term development. At the same time, due to the amateur nature of the local construction teams, new houses have common problems of insufficient anti-seismic or thermal performance (Pitts, 2016). Action plans therefore needed to balance between those involving self-reliance and knowledge bases from villagers, and knowledge support from professionals available from outside the village.

When international sustainability assessment methods were first introduced, the concept of 'sustainability' was perceived as a new western idea that could be adapted in the Chinese context. Whilst the concept of 'sustainable design' as a newly translated phrase from English can contribute to inspire Chinese thinking and help to introduce systematic methods for sustainable design and construction; the knowledge of 'sustainability' should not be considered as a totally new imported idea, but one that has its roots and knowledge base in historical change evident in various places (Pitts, Gao, 2014). Lessons can be learnt from previous experience. In cities, the knowledge bases in the past had rather different impacts on development. Chongqing city as a case study will be discussed in the following section.

Urban development in cities

The early central planning system in China had little influence from market forces and as a result the city's social space characteristics were homogeneous and balanced during the 1950s and 1960s. During this period, learning from the architectural approaches favoured in Russia to develop 'socialist content and national styles', the main representatives of important public buildings in different regions were large pitched roofs with monumental scale. With limited materials and funding, however, only small scale constructions were built for general public buildings and the design and construction largely relied on the locally available materials. Building design initially took account of the local climate and topography though during the Cultural Revolution period from the 1970s to the 1980s, there was very limited construction activity. Despite this, architects in different regions had tried to understand and incorporate regional traditions within the given economic conditions. In the context of scarcity of resources, the buildings for those periods were characterized by simple economical design. Pragmatic methods were adopted for regional architectural design and the methods which were known from experience to function adequately in traditional designs were favoured.

One design element here does have better environmental design outcomes, for example, internal courtyards were used in public buildings, learning from traditional houses, to create forms that were not only consistent with tradition but also improved natural lighting and ventilation, and created fluid spaces. Over these periods, in an endeavour to produce regional, national, and indigenous buildings, architects designed with common characters to suit local topography, geomorphology and climate. In this they would make use of local materials, low energy and simple construction methods; in so doing, they also inherited traditional forms and styles, and employed technical, cultural and intellectual methods that were able to provide inexpensive buildings. Similar to the rural areas where shared knowledge bases of farmers in a village have evolved in relation to new materials and technologies, in cities, one of the traditions has been followed is the way to distribute knowledge of good practice. Very often good design prototypes and requirements were promoted as examples for others to follow in the region. This was done by organising design competitions to identify premier design solutions and these were followed by local government policies and planning strategies for enforcement. The mass production methods proved to be efficient to create change, however, rapid developments also led to problems. Limited numbers of rather simplified working models were applied to a whole region, and many of the models lacked consideration of the diversity of the local conditions and were not linked to the preference and local knowledge of the user groups. The rapid urbanization since the 1990s in China has encouraged numerous examples of large-scale construction development in cities, and this has resulted in more varied and sometimes less satisfying quality of buildings and urban spaces.

Urban changes in Chongqing

Taking Chongqing as an example; the city is surrounded by mountains and defined by the confluence of two rivers: the Yangtze and Jialing Rivers pass through the city, and this forms four terrains inside the city. Due to the limits of the land capacity, buildings built along the hillsides have created the strong visual characteristics of the city (Figure 3). During the period of rapid urban development, many small lanes and steps which used to run up and down the hills have been erased, together with the small houses built on either sides of the steps.

Instead, high rise buildings, large shopping centres, and offices buildings have been constructed along wide new roads that are only suited for car transport.

Figure 3. Buildings along the sloping land in Chongqing, photo by Guo Chen.

Scholars argue that the original small and irregular layout of the public space and vernacular houses reflected the beneficial diversity of urban social life (Yang, 2017). For example, historically houses situated by the river banks and built for working class people were constructed with floors supported by stilts from the lower lying land. Those houses were called Diaojiao Lou (stilt houses) and have been promoted as the representation of local regional buildings. The earliest Diaojiao Lou can be traced back to the Eastern Han Dynasty. Most existing Diaojiao Lou were built in the 1940s and 1950s, however the majority of Diaojiao Lou have now disappeared. As timber structures, those houses could not last long without maintenance and renovation. In 2005, a new commercial street was built to learn from the traditional elevated street form (Liu, 2002), despite building from concrete, its visual forms are similar to the Diaojiao Lou's elevated floors, for visitors to experience the sensation of a pedestrian in the air (Figure 4). A contradiction exists however as those new buildings function as contemporary commercial streets that do not involve the traditional social networks.

Figure 4. Hongya Dong shopping center in Chongqing, photo by Guo Chen.

The phased programmes found in modern design and building schedules also led to separate knowledge bases between designers, manufactures and builders. In the field study in Chongqing, it was found that within a relatively short period of post occupancy period, a relatively large percentage of renewable facilities or materials failed or were changed. For example, plants died on green walls due to the failure of the watering system. It may be easier to design to incorporate new innovative ideas and technologies to meet sustainable requirements, but it takes a much longer period for the construction and manufacturing sectors to gain sufficient knowledge and experience to design and built for the local realities.

Consumers also based decisions on their knowledge and experience to choose and maintain energy saving products.

Different provinces have their own green building assessment criteria for supporting and developing green buildings based on local realities. The “Evaluation Standards of Green Buildings in Chongqing” was published in 2009, to be implemented from 2010. It required that all new public buildings invested in by government must comply with the Green building standard from 2014. However, despite the significant increase of new green buildings, they still account for a small percentage compare to the overall increase of the building sector in Chongqing. To help explain further the situation it should be understood that when the concept and theories of sustainable design were first introduced to China from the West, they were perceived as a new design movement. The general public associated ‘sustainable buildings’ with higher cost because of the better living standards they provided. It is often perceived that higher cost of sustainable buildings may be paid by developers whereas the long-term benefits are considered to go to occupants. Therefore incentive and mandatory regulations are needed to encourage stakeholders. However, this does not mean that previous knowledge from regional design needs to be sacrificed for financial reasons. Traditional regional buildings respected the site condition, took care of daily lives, habits and rituals; various design and plan strategies were also employed to reflect, respect and represent the diversity in the social life of inhabitants. Rather than create a ubiquitous form of large scale skyscrapers and public space, designers and developers can benefit from the past experience. Appropriate use of small neighbourhood divisions and verying building types could be used to enhance the characteristics of the site and community memory, and reflect prevalent diversified society.

Conclusion

This paper has examined some of understandings derived from cultural and social studies of rural settlements of Yunnan and also identified the urban heritage in Chongqing City, which highlighted the importance of knowledge bases that communities and individual had regarding what is called “sustainable development” today.

In rural areas of Yunnan Province where agriculture still provides the primary income for villagers and traditional social networks in villages are relatively intact, the classification of houses derived from the studies of the ethnic groups in the 1950s and 1960s provides knowledge bases for local government policy and planning strategies. Shared local knowledge within the rural communities could be described as a cohesive form of local knowledge capital.

In Chongqing city, before the 1980s, the planning economy system in China and the scarcity of the resources led to economical architectural design and construction methods that suited the local conditions. However, after the 1990s, a large number of building designs in urban areas focused more on the visual and size impacts than on sustainable design methods. At the same time, the concept and theories of sustainable design were perceived as a new design movement introduced from the West, and as a result were often associated with higher costs and luxury living.

This study examined the knowledge distinguishing between designers and builders and between designers and users. Field studies in both villages and cities in China demonstrate that it may be easier to design to incorporate innovative ideas and technologies to meet sustainable criteria requirements, but it takes a much longer period for the construction and manufacturing sectors to gain sufficient knowledge and experience to design and built for the local realities. Consumers also have preferences and influence actions to accept lifestyles impacting on energy use following knowledge gathered in the past. The combined planned economy and the market economy systems in China therefore requires integrating with the knowledge capital, along with other aspects of environmental and technological awareness in order to gain understanding provided from historic cultural and social studies of regional buildings. Therefore it is argued that the social and cultural aspects of 'sustainability' should not be considered as a new initiative, but one that has had its roots in the historical changes of build environments which have occurred in specific places. The social and cultural indicators for sustainable assessment methods can therefore be identified and constructed from studies of the historical transformation of the place.

Abstract: The external environmental conditions have an important effect on the thermal performance and durability of the building envelope. This study, which constitutes part of a multidisciplinary research program dealing with the environmental behavior of traditional buildings in the urban center of Nicosia, Cyprus, aims to investigate the hydrothermal performance of an external stone masonry wall of a listed traditional building. For the purpose of the present research, in-situ long-term monitoring was carried out. The monitoring included the indoor and outdoor environmental conditions of a southwest oriented room situated towards the street; furthermore, the west wall of the room was monitored with temperature/moisture probes installed at various locations along its thickness and height. The experiment was complemented with laboratory measurements of the thermophysical (thermal conductivity, porosity, and sorptivity) properties of the main masonry material, i.e. a local highly porous and absorptive calcarenite. Rising damp height, time of wetness, thermal inertia and decrement factor were calculated based on the laboratory and in-situ measurements. The results were analysed in terms of existing standards and analytical equations. The calculated time lag for a period of 24 hours was estimated at approximately 4 hours; however, in situ monitoring allowed the investigation of time lag for a period of 72 hours, showing that this was approximately 28 hours. The height of rising damp was estimated at 4 m and the mean residence time for the movement of water through the wall at 85 days. These results may be used to evaluate the overall thermal performance of the building and the durability of the masonry wall under investigation. They may also prove useful in future relevant studies.

Keywords: stone masonry wall, historic building, hydrothermal performance, time-lag, rising damp

Introduction

Energy efficiency and humidity have a significant importance in building science. Various studies focus on the effects of heat, air and moisture distribution in buildings, as well as on indoor air quality and human comfort (e.g. Holm 2008, Philokyprou et al. 2013). Traditional buildings have proved to be robust, durable and adaptable due to a series of environmental design strategies adopted in vernacular architecture (Oikonomou and Bougiatioti, 2011). One such environmental design strategy relates to the thermal inertia of traditional building materials, which contributes to a delay in heat transmission and to the restriction of temperature deviations between the external and internal surfaces of the building envelope; thus, establishing more stable indoor thermal conditions and consequently reducing the annual energy demand (Ferrari 2007, Orosa and Oliveira 2012, Martin et al. 2010). However, water movement and humidity in masonry walls affect the thermal performance of the building envelope and are important controlling factors of material deterioration. Therefore, understanding moisture movement is critical for assessing the durability of a structure and for establishing effective heritage conservation.

This study, which constitutes part of a multidisciplinary research program dealing with the environmental behavior of traditional buildings in the urban center of Nicosia, aims to investigate the hydrothermal performance of an external stone masonry wall in a listed traditional building located in Nicosia, Cyprus.

Methodology

With the purpose of studying the hydrothermal performance of the masonry wall under study, in-situ long-term temperature/moisture monitoring along its thickness and height were carried out from October 2014 to December 2015; these were complemented with laboratory measurements of the main building material of the stone wall. The building under study is constructed of 50 cm thick stone masonry walls with rubble infill. The stone is a local calcarenite or unsorted biosparite quarried from the Pliocene-age Nicosia Formation (Modestou et al., 2016). It has a large average grain size and it is very loosely cemented with sparry calcite matrix resulting in a coarse, friable texture. The western wall of the building, near its southwest corner, was chosen for the placement of temperature/moisture probes, as this wall was more exposed to the external environmental conditions (Fig. 1a).

Laboratory measurements and calculations

For the determination of the thermophysical and hydro properties of the local calcarenite i.e., the main building material of the wall under study, a specimen with dimensions 20 x 20 x 3 cm was selected. The thermal conductivity (λ) and specific heat capacity (Cp) of the sample were measured using the ISOMET 2104 instrument. Thermal diffusivity (α) was further calculated as a function of the above properties and density (ρ), according to the following equation:

$$a = \frac{\lambda}{\rho \mathrm{Cp}} \qquad \text{(eq.1)}$$

Its open porosity was estimated using the method described in EN 1936; this implies saturation with water under vacuum. The water sorptivity was measured following the method described in Hall and Hoff (2012). Table 1 summarizes the thermophysical properties of the local highly porous and absorptive calcarenite.

Table 1. Thermophysical properties of the stone material

Density ρ (kg/m^3)	Thermal Conductivity λ (W/mK)	Specific heat capacity Cp (kJ/kgK)	Thermal diffusivity a (m^2/s)	Open porosity (%)	Sorptivity ($mm/min^{1/2}$)
1555	0.538	0.887	$3.91x10^{-7}$	42.3	7.09

In order to evaluate the thermal inertia effect in the high porosity stone masonry wall and its effectiveness in reducing energy demand, two dynamic indicators, i.e. the time lag and decrement factor, were used. These are very important characteristics to determine the heat storage capabilities of any structural element. Time lag represents the time that a heat wave needs to spread from the outer to the inner surface, whereas, the decrement factor shows the decreasing ratio of its amplitude during heat transmission. Several studies focus on the estimation of these factors using numerical methods (Asan 2006, Stephan et al. 2014, Collet et al. 2006). The time lag (φ) and decrement factor (f) in this study were therefore calculated using the following equations proposed by Asan (2006):

$$\varphi = \begin{cases} \tau\,(Tsi_{max}) - \tau\,(Tse_{max}) & for\ (Tsi_{max}) > \tau\,(Tse_{max}) \\ \tau\,(Tsi_{max}) - \tau\,(Tse_{max}) + P & for\ (Tsi_{max}) < \tau\,(Tse_{max}) \\ P & for\ (Tsi_{max}) = \tau\,(Tse_{max}) \end{cases} \quad \text{(eq. 2)}$$

$$f = \frac{Asi}{Ase} = \frac{Tsi_{max} - Tsi_{min}}{Tse_{max} - Tse_{min}} \quad \text{(eq. 3)}$$

where Tsi_{max} and Tse_{max} are the times when the interior and exterior surface temperatures respectively reach their peak value within a period of 24 hours.

For the calculation of the steady state height of rising damp the equation proposed by Hall and Hoff (2012) was used:

$$hss = S\,(\frac{b}{Ne\theta w})^{1/2} \quad \text{(eq. 4)}$$

where hss (mm) is the height of rising damp, b (mm) the thickness of the wall, S ($mm/min^{1/2}$) the sorptivity, θw the volume fraction porosity of the material, e (mm/min) the evaporation rate and N the sides of the wall exposed to evaporation (set at 2 for evaporation from both sides).

The mean residence time for the movement of water through the wall was calculated using the following equation (Hall and Hoff, 2012):

$$t95 = \frac{3b\theta w}{Ne} \quad \text{(eq. 5)}$$

In situ monitoring

The variation of temperature was measured along the height and depth of the wall section; humidity was investigated along its height alone (Fig. 1b). The temperature sensors were nickel alloy type K thermocouples connected to a multi-channel data logger (PicoLog TC-08) which was activated every 10 minutes for a second. These were installed sideways at various locations along the thickness of the stone, i.e. at 0, 2, 25, 50 and 100%, at a height of 80 cm, as well as along the wall's height at 15, 30, 60, 80, 100 and 120 cm above the street level. Moreover, a thermocouple was installed on the outer wall surface, in a position that was protected from direct sunlight (P7/Ext.) (Fig. 1c). Good adhesion of the sensors to the wall was ensured through the use of elastic rubber, thus preventing thermal bridging. For moisture measurements, insulated stainless steel pins connected with two resistance-type moisture sensors (ceramic pins) were used and connected to a multi-channel data logger (ADC-20/ADC-24). These sensors were mounted on the inner surface of the wall in positions extending up to 120 cm from the floor level, as shown in Figure 1b. The moisture sensors were connected to a data acquisition system, which was automatically activated every 10 minutes for a duration of 5 seconds. The average of 5 individual measurements was calculated discarding the first and last measurement.

The exterior weather conditions were monitored with a 30-minute sampling frequency, using a weather station (Davis Vantage Pro2) installed at about 2-3 meters above the roof of the building under investigation. Interior air temperature and humidity levels were also recorded at a height of 1.5 meter in the middle of the room, to avoid thermal convective effects of walls, using calibrated EL-USB-LCD data loggers.

Results and Discussion

Wall thermal behaviour analysis

In the framework of the current research, the dynamic effect of thermal mass was estimated, analyzing the in-situ monitoring temperature data along the thickness and height of a stone masonry wall. For the calculation of the dynamic indicators, the position P5/100 cm was selected, since this was expected to be less affected by rising damp. Selected results from the cold period associated with rainfall events (early February 2015), intermediate period after rainfall events (early March 2015) and warm period without rainfall events (late May 2015) are hereby presented. The average values and standard deviation of the indicators calculated according to aforementioned equations are shown in Table 2.

Table 2. Average and standard deviation of experimental time lag and decrement factor

Period	Description	Time lag ϕ (h)	SD	Decrement factor f (-)	SD
29.01-15.02.2015	Rain Stable temp. 29.01-08.02.15 Temp. drop 09.02-15.02.15	4:40	2:45	0,113	0,057
01.03-10.03.2015	No rain Stable temp.	3:27	1:46	0,13	0,119
15.05-28.05.2015	No rain Temp. rise 15.05-20.05.15 Stable temp. 21.05-28.05.15	3:45	1:01	0,1	0,021

As observed, time lag values vary depending on the particular weather conditions i.e. raining events, wind velocity, solar radiation, relative humidity, and rapid temperature change. During the period when the temperature was stable (21.05-28.05.2015), the maximum internal surface temperature Tsi_{max} occurred around 18:30, while the maximum external surface temperature Tse_{max} occurred around 14.30. This indicates a time lag of approximately 4 hours within a period of 24 hours. The decrement factor was estimated at 0.1 and it is in line with the value reported by Asan (2006), who states that wall thicknesses above 30 cm show decrement factors near zero. The results are also in line with other studies which evaluate the thermal inertia of stone buildings, such as the research of Stephan et al. (2014) which demonstrates a time lag of 4 hours and a decrement factor of 0.1. However, in situ monitoring allowed the investigation of time lag for a period of 72 hours, showing that this was approximately 28 hours, i.e. 4+24 hours (comparison between P5/100 cm and P7/Ext. in Fig. 1c). The standard deviation of the time lag was estimated at 1 to 2 hours in no rainfall periods; whereas during rainfall events this increased to about 3 hours. Larger variations of time were observed in the minimum values.

Figure 2 depicts the temperature flux through the wall under investigation, at all monitoring locations, for a period of 5 days in May 2015. During that period, a steep decrease of external temperature, followed by a steady increase, allowed some interesting observations to be derived. Looking at the time when the maximum temperature occurred along the thickness of the wall, starting from the external surface (P7/Ext.) towards the interior (4, 4c, 4d), the following is observed: T_{se_max}≈14:30, $T_{si50\%\_max}$≈23:30, $T_{si25\%\_max}$≈23:30; whereas, $T_{si0\%\_max}$ occurred at around 18:30. The correspondence of the time when the heat wave hit every internal position in relation to the exterior shows that the peak is observed on the following day. It is interesting to note that the internal surface $T_{si0\%\_max}$ achieved its peak temperature value earlier than the sensors at 25% and 50% monitoring locations. This is attributed to the effect of ventilation from the *arseres* i.e., clerestories, which were always open during the recorded period, allowing the internal environment to be exposed to the external.

The calculated time lag for the sensors at 25% and 50% monitoring locations was 33 hours. It is worth mentioning that the thermocouple in position 4b $T_{si2\%}$ shows similar values with the values of the external environment. This may be the result of the placement of the thermocouple in a joint composed of a different material (possible gypsum or clay mortar); therefore, its behavior is ignored. Finally, the temperature on the plaster surface $T_{si\_plaster}$ (4pl) shows similar behaviour with the inner surface of the stone wall $T_{si0\%}$. In terms of temperature differentiation along the height of the wall, it was observed that the temperature slightly increased with height (1-2 K difference between P1/15 cm and P6/120 cm). This is the result of moisture content differentiation along the height of the wall. Earlier rainfall events (12-14.5.2015) led to an increase in the height of rising damp, thus decreasing the heat capacity of the material and consequently the temperature at those monitoring points.

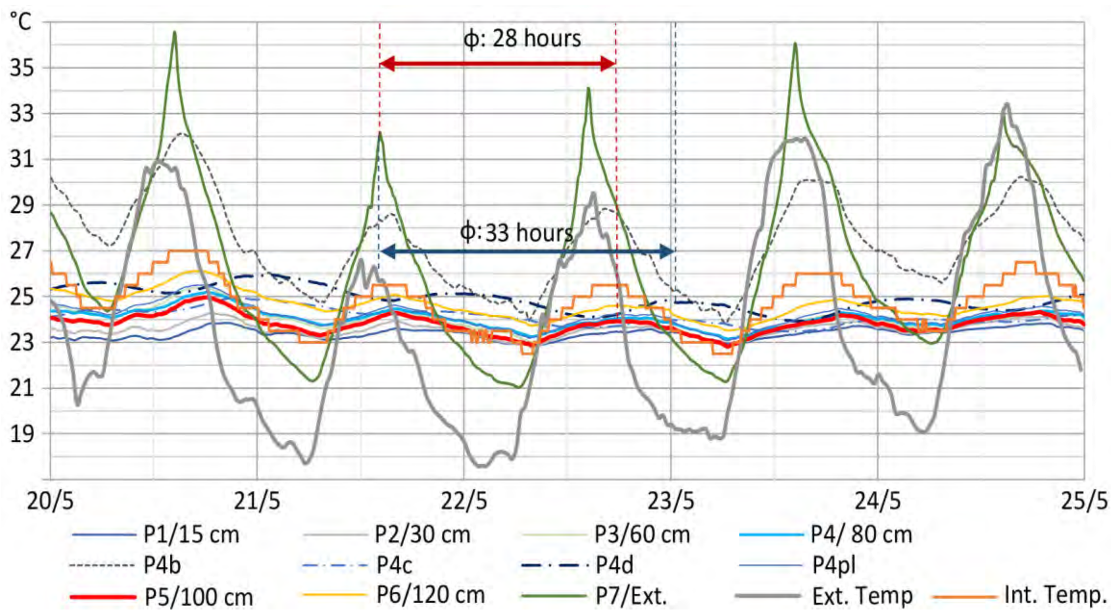

Figure 2. Hourly temperature distribution in all sensor locations during 5 days in May 2015.

Wall moisture behaviour analysis

The building under study exhibits moisture problems at significantly high levels (Fig. 3); thus, an interesting issue for further investigation was the examination of the height of rising damp and of the residence time for the movement of water through the wall.

The height of rising damp on the interior walls follows the pattern of shading line at the exterior wall (Fig. 3). In the middle of the room, around the window, this height exceeds 2.80 m; this is significantly higher than in the corner of the wall, where the in-situ monitoring had taken place. This may be a result of enhanced evaporation in the corner of the room, due to uncontrolled air flow in the junction between the two walls. Building corners and parapets are especially susceptible to wind currents, because the wind induces very steep pressure gradients in these areas (Straube, 2001). This can also be confirmed from the thermal image which illustrates increased heat losses in the corner (Fig. 3c).

Figure 3. (a) External view and (b, c) internal surfaces of the southwest room under study showing clear signs of moisture problems.

In the course of the year, the height of rising damp changes continuously in response to imbalances between the inflow (at the base of the wall) and the outflow (by evaporation at the wall surface) of moisture. Table 4 shows the effect of evaporation rate on the height of rising damp for the wall under study. The annual mean height of rise was estimated at 4 meters.

Table 4. Effect of evaporation rate on the height of rising damp

	Evaporation rate (Cox, 1999) (mm/min)	Height of rising damp (m)	Mean residence time (days)
Annual	0.0022	4	85
January	0.0007	7	267
July	0.004	3	46

In order to confirm the calculated height of rising damp, continuous moisture monitoring started in October 2014 and continued for 457 days. As observed in Figure 4, different rainfall events took place during the recorded period: short rainfall events or showers followed by a dry period of several days (e.g. 1.11.2014, 26.11.2014), long wet periods (09.12.2014-15.03.2015) and dry periods (6.6.2015-26.11.2015).

Figure 4 gives a graphical overview of the moisture content pattern in mV at 12:00 for the period of monitoring, together with the daily cumulative rainfall events. As shown, the moisture content differentiates along the height of the wall. Specifically, the wetting indicator decreases as the distance from the ground level increases, as expected (Hall and Hoff, 2012).

The area around P2/30 cm appears to be saturated at all times, as it is situated below the road level. Moisture in P6/120 cm is generally stable with low voltage, demonstrating no or little moisture content. Positions P4/80 cm and P5/100 cm show the highest fluctuations, demonstrating the effect of rising damp, and the zone where decay and salt crystallisation is expected to occur. The in-situ monitoring results are, nevertheless, not consistent with the values given by steady state calculations. According to the in-situ monitoring, the rising damp height at the area under investigation should be lower and should reach approximately 80 cm. This may be the result of increased evaporation rate at the corner.

The influence of the daily recurrent pattern of RH is reflected in the wall moisture content. In situ monitoring shows that positions P5/100 cm and P6/120 cm are directly affected from external environmental conditions portraying large variations. For example, on 21.02.2015 the external relative humidity drops to 35%, leading moisture content in positions P5/100 cm and 6/120 cm to low levels (42 and 17 mV respectively compared to the mean values of 55 and 35 mV under non-rainfall events). External RH linearly affects the drying rate of porous materials (Hall et al. 1984).

The detailed examination of the moisture changes of the wall during the period under investigation showed that, the estimated time for water to travel in position P4/80 cm was 56 days, whereas in P5/100 cm it was 90 days. The time for the desorption of position P5/100 cm was less, i.e. 55 days according to the in-situ monitoring (12.11.2015).

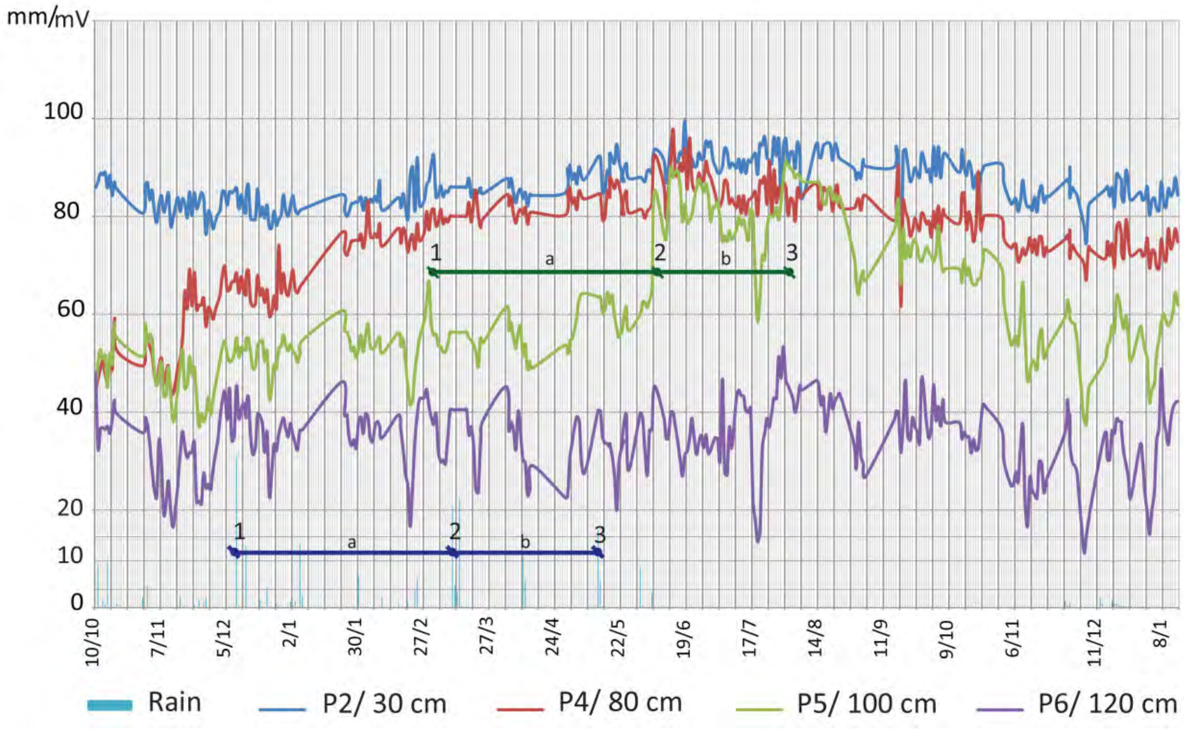

Figure 4. Graphical overview of moisture content pattern in mV at 12:00 for the period of monitoring, together with daily cumulative rainfall events.

Conclusion

Environmental conditions have a significant effect on the thermal behavior of buildings and on the durability of building envelope materials. The high time lag (28 hours) and low decrement factor (0.1) values estimated in this study confirm the thermal stability of the indoor environment of traditional stone structures. It is worth mentioning that rainfall events lead to absorption/desorption of moisture, leading to significant deviations in the thermal time lag. This shows the close relationship between rain events and absorption/desorption of moisture by stone masonry walls. The calculated height of rising damp was estimated at 4 m and the mean residence time for the movement of water through the wall at 85 days. However, in situ monitoring and observation allowed further investigation showing the dynamic effect of environmental conditions at specific areas of a building.

Design to Thrive

Spatial and environmental delight in Northern Vietnam houses for contemporary application

Long Hoang[1] and Benson Lau[2]

[1] Institute for Building Science and Technology, Vietnam, email: duclonghoang@gmail.com
[2] Faculty of Architecture and the Built Environment, University of Westminster, London, United Kingdom, email: B.Lau@westminster.ac.uk

Abstract: Published studies suggested that the environmental design strategies adopted in vernacular houses in Vietnam are spatially flexible, environmentally efficient and well adapted to local natural and cultural context. Investigating two representative houses in Northern Vietnam, this study aims to explore the spatial delight, thermal and daylighting performances of this type of houses and assess the impacts of environmental design strategies on the thermal and visual comfort for the occupants.
Computer aided parametric analysis of the two selected houses was conducted by using IESVE to evaluate their thermal and daylighting performance. Additionally, a representative contemporary shop-house was also investigated and tested for comparative analysis. The thermal and daylighting performance of all three cases were benchmarked against relevant environmental design standards. Based on the research results, a reconceptualised shop-house was proposed and evaluated to explore the significance and contemporary relevance of the environmental design features and strategies identified in the vernacular houses.
The research findings indicate that vernacular houses in Northern Vietnam respond well to the local climatic challenges and offer desirable thermal and visual comfort. Moreover, the vernacular environmental strategies adopted in these houses can be selectively re-adapted to help improve the thermal and daylighting performance of the contemporary urban shop-house.

Keywords: spatial delight, vernacular environmental strategies, thermal comfort, visual comfort, contemporary shop-house

Introduction

Vernacular houses in Northern Vietnam, as climatically, socially, and economically adaptive accommodations, form an important architectural legacy of Vietnam (Hoang, 2013). However, there is little published holistic investigation of the thermal and daylighting performances of the vernacular housing typologies in Northern Vietnam. Most studies focused on only one housing type which does not offer a conclusive understanding of the spatial and environmental delight in these houses. Also, systematic and evidence-informed studies of the effectiveness of the environmental strategies are scarce. Furthermore, there is a need to identify and re-apply the workable vernacular environmental strategies to contemporary buildings. Lastly, the lack of workable research methodology for assessing visual comfort and irrelevant and obsolete parameters used to explore the luminous environment indicate a need for a rigorous and quantitative light study for vernacular houses in Northern Vietnam.

Research objectives and methodology

Research objectives

In this research, two research objectives were proposed: firstly, assessing the thermal and visual comfort in vernacular and contemporary housing in Northern Vietnam, and secondly, evaluating the effectiveness of the application of traditional environmental strategies in contemporary shop-houses.

Research methodology

This research was conducted based on three case studies. Each case study represented one housing typology of the following: vernacular rural house, vernacular urban shop-house, and contemporary shop-house.

The research process involved three successive stages. The first stage was to analyse the environmental design concepts and architectural features of the three cases. The second stage was to explore the environmental performances of the vernacular rural, the urban dwellings, and contemporary shop-house through computer aided simulation, computational modelling, dynamic and steady state simulations. Subsequently, the simulated data were processed and the overheating hours (OH), cooling degree hours (CDH), heating degree hours (HDH), and Useful Daylight Illuminance (UDI) were analysed. These performative assessment criteria of all test cases were compared. Furthermore, they were benchmarked against TM52, CIBSE Guide A, and CIBSE LG10. The third stage involved developing, testing, and proposing a theoretical South-facing shop-house model which embraced the workable vernacular environmental design principles and features through in-depth building performance analysis.

Typical vernacular rural house

The model for the typical vernacular rural house was nominated by Hoang (2013, p.373). Ly (2012, p. 24) also agreed that this house model was representative of rural housing in Northern Vietnam.

Spatial delight in the typical vernacular rural house

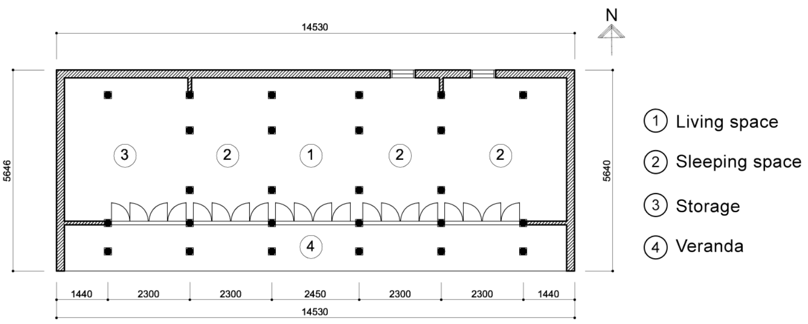

Figure 1 Floor plan of the typical vernacular rural house

The spatial layout of the typical vernacular rural house revealed a culturally and environmentally integrated architectural design (Figure 1 and Figure 2). Culturally, the spatial arrangement which places the sacred altar in the living space, at the centre of the house, honours their ancients. Environmentally, the narrow West façade helps reduce the wall surface exposed to direct sunlight during hot hours in summer while the long South façade takes advantage of the solar gain in winter and capture the South-East prevailing wind.

The high roof and large open doors enhance buoyancy-driven ventilation and keep the indoor spaces cool at night. In addition, the steep slope of the roof helps discharge water quickly. Another important feature of this type of house is the roof overhang. It provides shading, acts as a buffer space between the inside and outside and permits desirable indirect light to lit the living spaces and direct solar gain in winter.

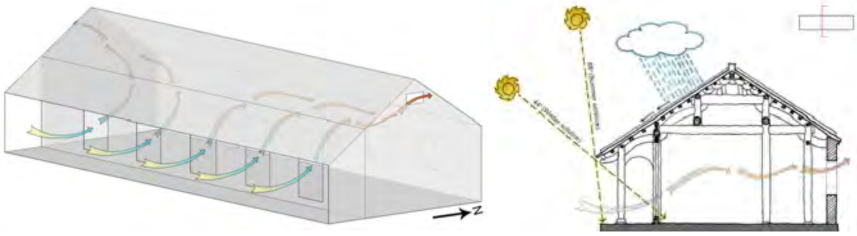

Figure 2 Buoyancy-driven ventilation in the vernacular rural house

Thermal performance in the typical vernacular rural house

Table 1 **Error! Reference source not found.**shows that the indoor thermal condition in the rural house is not thermally acceptable in summer. Overall, thermal comfort is achieved for 67% of the typical year.

Table 1 The simulated percentage of OH and daily CDH against CIBSE Guide A and TM52

	CIBSE Guide A	TM52	Simulated figure
Percentage of overheating hours (%)	< 1	< 3	16.3
Maximum daily CDH (degree hours)	Not specified	< 6	41
Percentage of underheating hours (%)	Not specified	Not specified	17

The predicted OH and CDH during most occupied hours (Figure 3) were much lower than the overall values. This suggests that the main objective of the vernacular rural design was to increase night cooling and prioritise nocturnal thermal comfort.

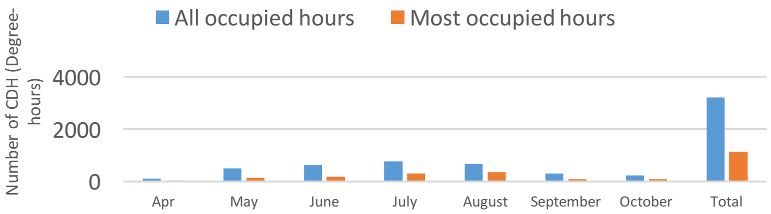

Figure 3 Cooling degree hours in total and in most occupied hours

Daylighting performance in typical rural house

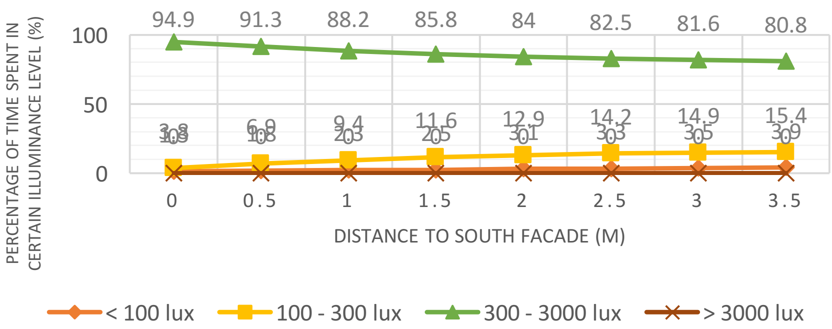

Figure 4 UDI by distance to main doors (Thresholds derived from CIBSE LG10)

The daylighting performance of the typical rural house is acceptable. Considering the UDI of the living space and the criteria of CIBSE LG10, the typical vernacular rural house was well-lit. Most points on the working plane achieve at least 80% of its occupied time with illuminance from 300 to 3000 lux (Figure 4).

Typical vernacular urban house

The old house at 87 Ma May Street was selected to represent vernacular urban housing for this research after a background study of the history of housing in Hanoi. Residences built in Hanoi before the 19th century retained typical local architectural features (Tran, 2008). Drawing an agreement with this claim, other authors emphasised that only shop-houses constructed in Hanoi Old Quarter before or in the 19th century should be considered purely vernacular (Management Board of Hanoi Old Quarter Heritage, 2014). The selected house was built in Hanoi Old Quarter in the 19th century. Thus, it is representative of Northern Vietnam traditional urban houses.

Spatial delight in the typical vernacular urban house

The spatial arrangement and floor plans of the old house at 87 Ma May Street are shown in Figure 5.

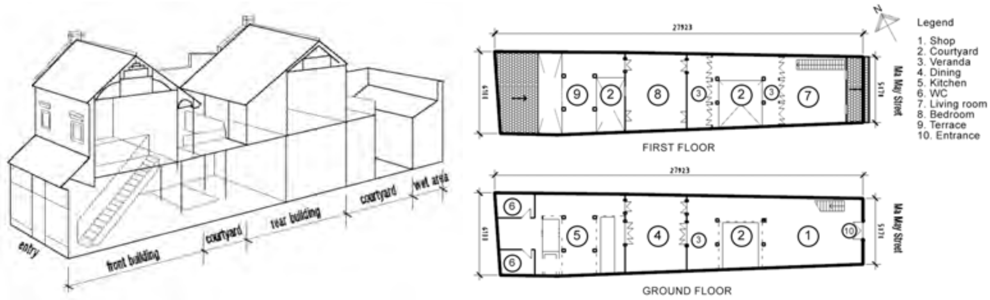

Figure 5 Spatial arrangement of the House at 87 Ma May, Hanoi (Ly, 2012)

This house inherits some design features from the vernacular rural house, which include large opening doors, high and steep roofs, and verandas. The steep roof slope helps to control and discharge rainwater. The veranda creates a larger buffer zone shielding the living room and bedrooms from solar heat gain. The stack effect induced by the high ceiling and large openings enhance cross ventilation and night cooling strategies (Figure 6).

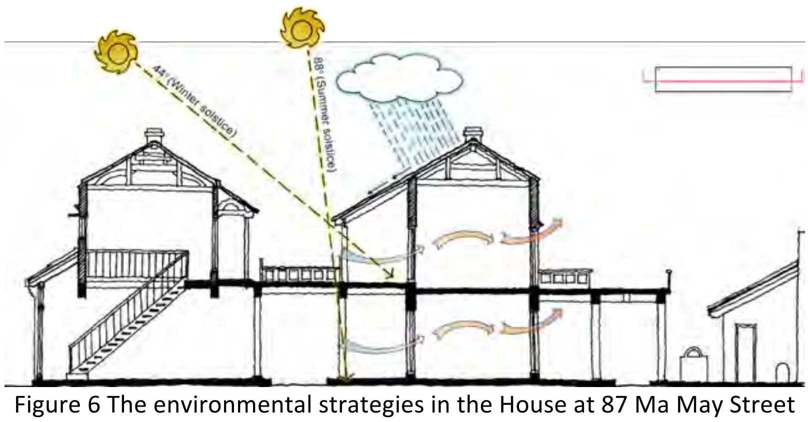

Figure 6 The environmental strategies in the House at 87 Ma May Street

Unlike the rural house, the urban house must accommodate both external and internal activities. Responding to this need, the builders applied a courtyard-centred layout. The courtyards allow cooler air to be supplied to main living spaces. Furthermore, they are the main sources of daylight and fresh air.

Thermal performance in the typical vernacular urban house

The traditional urban shop-house confirms the significance of night cooling in vernacular dwellings in Northern Vietnam. The large controllable openings to the internal courtyards can be closed during daytime and opened at night to benefit from night cooling. The percentage of OH and maximum daily CDH (Table 2) indicated that all rooms did not meet the requirements of TM52. Nevertheless, while the daily occupied time of the bedroom was 4 hours longer than the occupied time of the living room, the CDH of the living room surpassed the figures for the bedroom by vast margins (Figure 7). This supports the observation found in the rural house that vernacular environmental designs in Northern Vietnam focus on nocturnal thermal comfort rather than diurnal comfort.

Table 2 Percentages of OH and maximum CDH of main rooms in the House at 87 Ma May

	TM52	Living room	Main bedroom	Shop
Percentage of overheating hours (%)	< 3%	27.1	8	28.9
Maximum daily CDH (degree hours)	< 6	34	14	36

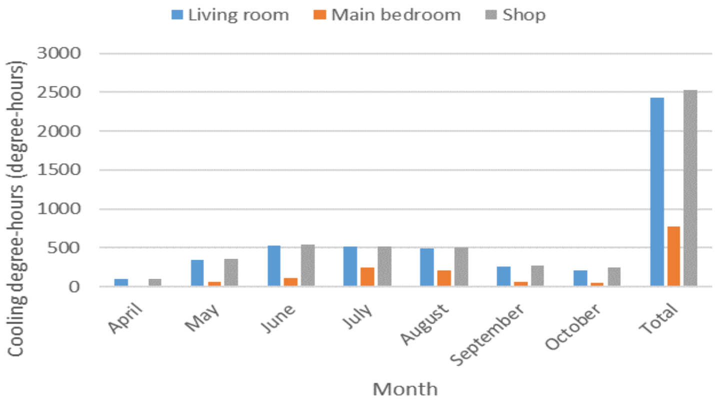

Figure 7 Number of CDH for different rooms in the House at 87 Ma May Street

Daylighting performance in the typical vernacular urban house

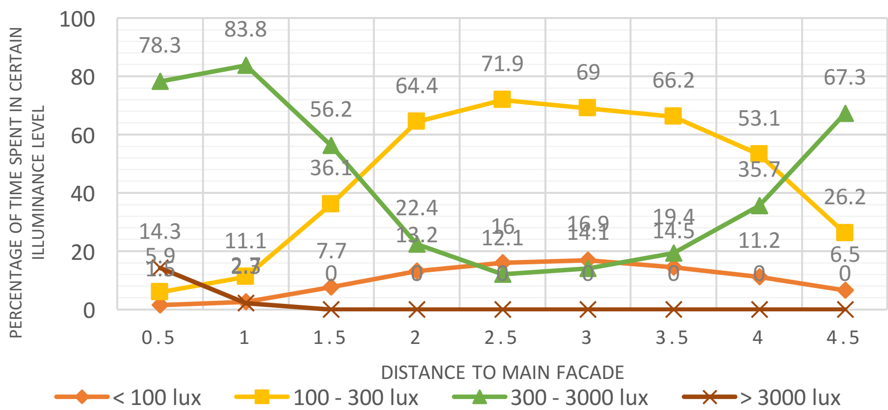

Figure 8 UDI in the living room of the House at 87 Ma May by distance to the main facade

The living room in the vernacular urban house shows a sophisticated daylighting strategy. Small windows on the South-East façade reduce undesirable solar ingress while the large openings to the courtyard ensure adequate daylight illuminance throughout the day. Most points on the working plane will experience the illuminance of 100 – to 3000 for 83.1% to 98% of the occupied time in a typical year (Figure 8).

Typical contemporary shop-house

Architectural features

The contemporary shop-house was selected for investigation due to its functional similarity to the vernacular urban house as shown in Figure 9. Spatially, it has the typical shop-house's rooms: shop, three bedrooms, two living rooms, a kitchen, and a veneration room.

Thermal performance in the typical contemporary shop-house

The percentages of overheating hours and underheating hours of main living and working spaces (Table 3) in the contemporary shop-house indicate that no room met the TM52 requirements. Thermal comfort in the contemporary shop-house is not achieved.

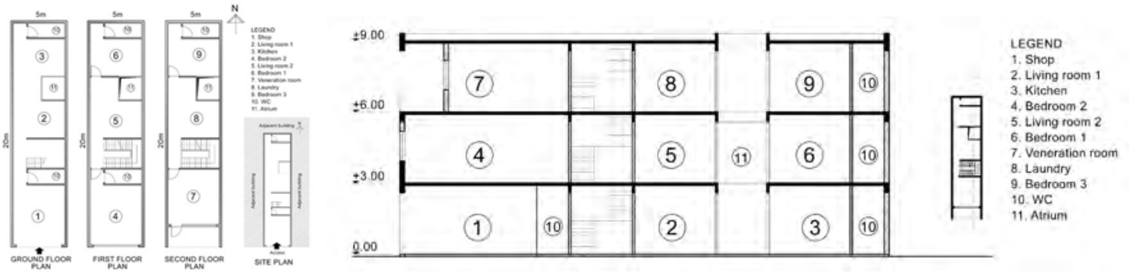

Figure 9 Floor plans, site plan, and longitudinal section of the typical contemporary shop-house

Table 3 Percentages of OH, UH and maximum daily CDH of the contemporary shop-house

	TM52	Living room 1	Living room 2	Bedroom 1	Bedroom 2	Bedroom 3	Shop
Percentage of overheating hours (%)	< 3%	3.1	1.2	8.4	15.3	12.4	31.9
Maximum daily CDH (degree hours)	< 6	2	11	6	14	11	30
Percentage of underheating hours (%)	unspecified	19.6	19.3	20.8	17.3	20.4	18.7

Daylighting performance in the typical contemporary shop-house

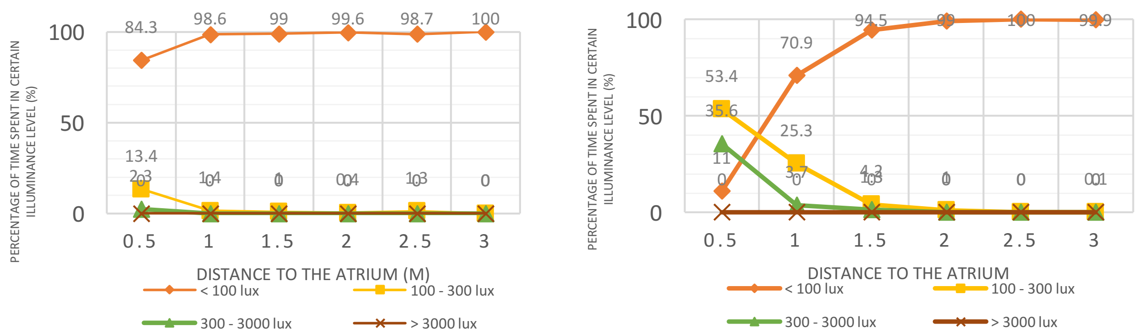

Figure 10 UDI of the living room 1 of the contemporary shop-house

The daylighting performances of the two living rooms are generally poor. Their working planes were predicted to receive less than 100 lux for 70 - 99% of the year (Figure 10).

Reconceptualised shop-house model

Spatial delight in the reconceptualised shop-house

Figure 11 Floor plans and environmental strategies of the proposed shop-house model

Based on the results of the previous case studies, a reconceptualised model is developed to respond better to occupants' spatial and environmental needs. This new model has only one living room on the first floor. The living room is exposed to the main street so that it can gain access to more natural light. All bedrooms, shielded by overhangs, are situated further away from the main street than the living room. Single-sided and cross ventilation and daylighting are allowed by properly sized windows and internal courtyards. The environmental strategies of the reconceptualised shop-house are illustrated Figure 11.

Thermal performance in the reconceptualised shop-house

The new proposed model clearly outperforms the contemporary one in terms of energy consumption and thermal comfort because of the combined outcome of all the applied vernacular strategies. Noticeably, there is a wide disparity of over 5000 heating degree hours between the proposed model and the contemporary one (Figure 12).

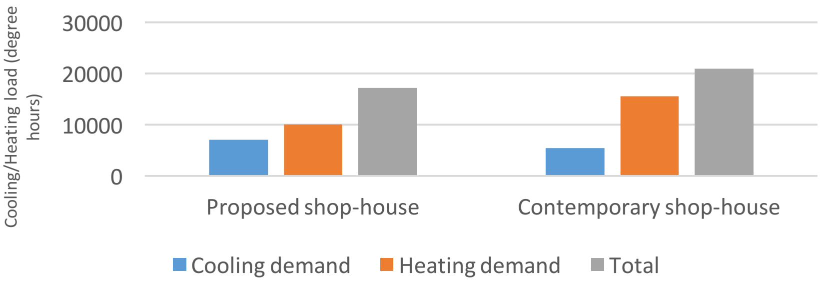

Figure 12 Heating and cooling degree hours of the contemporary and reconceptualised shop-houses

Except for bedroom 1, the cooling degree hours of bedroom 2 and 3 in the proposal are far lower than the contemporary bedroom demands. A similar observation is obtained in the heating degree hours (Figure 13).

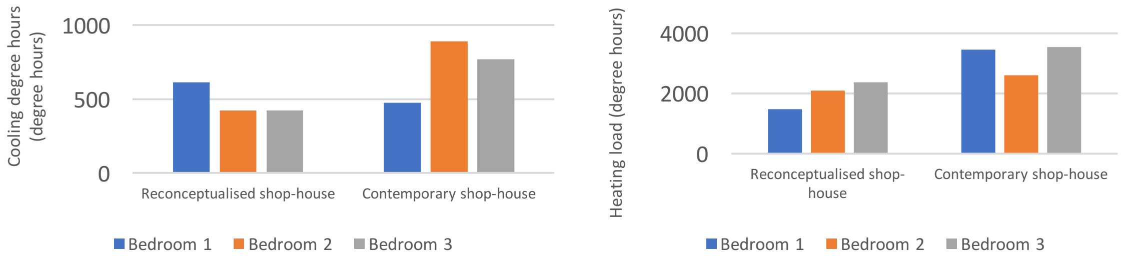

Figure 13 Cooling and heating degree hours of bedrooms in the proposed and contemporary shop-houses

Daylighting performance in the reconceptualised shop-house

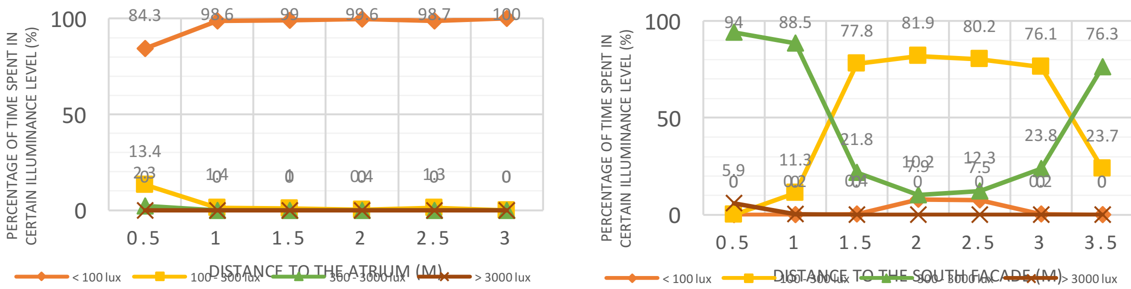

Figure 14 UDI of Living room 1 in the contemporary shop-house (right) and the reconceptualised one (left)

The daylighting performance of the proposed shop-house is much better than that of the contemporary house. The living room of the proposed house is predicted to benefit from acceptable (100 – 300 lux) or desirable (300 – 3000 lux) illuminance for 80% to 90% of daylight hours (Figure 14).

Conclusion

Environmental design strategies in vernacular housing in Northern Vietnam

The Environment design features identified in the vernacular housing in Northern Vietnam presents a workable approach to achieve the right balance between culture, functions, and human comfort. All the well tested vernacular environmental strategies, including courtyards, high-pitch roof, materials of low U-value, verandas, and window sizing, can be applied to contemporary shop-house design. The combined impacts of these solutions in a reconceptualised shop-house can be predicted to decrease about 25% of the total heating and cooling degree hours.

Application of vernacular environmental strategies in a reconceptualised shop-house

The effectiveness of vernacular environmental strategies in the newly proposed model indicates two important points. Firstly, the contemporary shop-house in Northern Vietnam can be reconceptualised into a more environmentally efficient model which not only accommodates contemporary spatial demands but also help mitigate thermal and daylighting discomfort. Secondly, vernacular environmental strategies can be further developed and re-adapted effectively to contemporary housing. However, the application may not be straightforward and would require an initial re-design of spatial arrangement and rigorous building performance analysis.

Thermal and visual comfort of housing in Northern Vietnam

As shown in the performative analysis, the typical vernacular rural and urban houses did not achieve thermal comfort. The first explanation for this phenomenon is that local builders gave more priority to heating demand than cooling. The second possible reason is that the selected standard to benchmark against might not be appropriate for the climatic conditions of Northern Vietnam.

The contemporary shop-house did not achieve thermal comfort because preventing increases in indoor temperature for thermal comfort is not sufficient in hot humid climate, and proper promotion of cooling is required.

All vernacular houses have good daylighting performance while the living rooms in the contemporary shop-house are not adequately lit. The main vernacular living spaces have good access to daylight because of the deliberately placed courtyards and large folding doors protected by extended eaves. However, the small atrium in the contemporary house does not offer many daylighting benefits.

Performance in Passive Climate Control of Traditional Archetype at a Tibetan Monastery

Lingjiang Huang[1], Jiayu Xiao[2]

[1] Department of Architecture, Wuhan University, Wuhan, China, huanglj@whu.edu.cn
[2] Department of Architecture, Wuhan University, Wuhan, China, aling_931@126.com

Abstract: Passive measures were employed in vernacular buildings to respond to local climate. Through long-term trial and error, certain fixed archetypes were gradually formed. They are worthy to inform modern design against the local climate. This paper presents a traditional Tibetan archetype that was employed in a three-story building in the Jokhang Temple. The basic pattern of the archetype is an enclosed atrium surrounded by dormitory rooms, while a large volume of skylight projecting the roof was adopted for purposes of natural lighting, ventilation etc. A perforated floor was further employed as a horizontal opening for the lower floor. The archetype provides complex passive solutions to manipulate indoor climate against the extreme climate. However, the performance has not yet been examined. The aim of this study is to first analyse the strategies of climatic control in this archetype. Then, by computer simulation, the performance of natural lighting and ventilation are evaluated. Later, the major factors of the archetype that have impacts on the performance are discussed. At last a traditional archetype in Tibetan local climate is summarized.

Keywords: traditional archetype, passive climate control, Tibet

Introduction

Vernacular buildings provided as comfort as possible indoor thermal environment by intelligence responding to local climatic conditions. Through long-term trial and error, the intelligence was developed into design strategies and gradually formed certain fixed archetypes. Numbers of studies on vernacular buildings have been conducted from the point of view of climatic responsive designs in various types. However attention on traditional archetypes are still limited, some of which have been proved to be effective through centuries and are also worthy to inform modern designs against the local climate. This paper presents a traditional archetype employed in the most important temple in Tibet-the Jokhang Temple built in Lhasa during the thirteenth century. The archetype provides passive solutions to manipulate indoor climate against local extreme climate. However, the performance has not yet been examined. The aim of this study is to first analyse the climatic responsive strategies in this archetype. Then, by computer simulation, the performance of natural lighting and ventilation of the archetype are evaluated. Later, the major factors of the archetype that have impacts on the performance are determined.

Primary features of climatic conditions in Lhasa

Tibet is located in the southwest region of the Tibetan Plateau with an average altitude of 4000m, while Lhasa is the largest settlement in Tibet with an altitude of 3600m and belongs to the Dwd climate or cold climate according to the global Koeppen-Geiger Climate classification (Yang, 2004) (Kottek et al, 2006).Climatic features of Lhasa includes annual low temperatures, intensive and long solar radiation, high diurnal temperature variations and windy weather. The mean monthly temperature is approximately -1.0°C and the daily lowest temperature in the coldest month can reach -13°C, the mean diurnal variation in the coldest month is greater than 13°C, the global solar radiation in is 610 MJ/m2. Lhasa is very dry throughout the year, and in winter, the average relative humidity is low at approximately 26.5%.The windy season in Lhasa covers nearly half the year and extends from December to April, with the highest velocity reaching 12m/s(China Meteorological Bureau, 2005).

Basic patterns of the archetype

The archetype for large single-storey space that are generally employed in Tibetan monasteries has been studied in previous study (Huang and Deng, 2016). However another archetype for multiple storey buildings is very unique in traditional Tibetan public buildings. A typical case is found in a three-storey building in the Jokhang Temple, which historically functions as the administrative office of the Panchen Lama and the monk dormitory on the first and second floor while the ground floor functioned as the storeroom with no occupancy (Xu 2016).The basic pattern of this archetype includes an enclosed atrium penetrating the first and the second floor, of which are surrounded by unit rooms and circulation areas. The top atrium has a large volume of skylight projecting the roof while the lower atrium has a horizontal opening on the floor above. This archetype was found to be presented in two different forms with a large and small atrium respectively as shown in Figure1.

Figure1. Two forms of the archetype

The size of the skylight and the area of the horizontal opening are in direct proportion to the area of the atrium and the floor. The horizontal opening in the large atrium is covered by wood grating and the size of each hole keeps very small around 120mm that is less than a human foot. The reason for the perforated floor other than an open courtyard might result from the purpose of separating the lower and upper space for privacy while retaining the path for airflow and lighting. Conceptual models are given in Figure2.

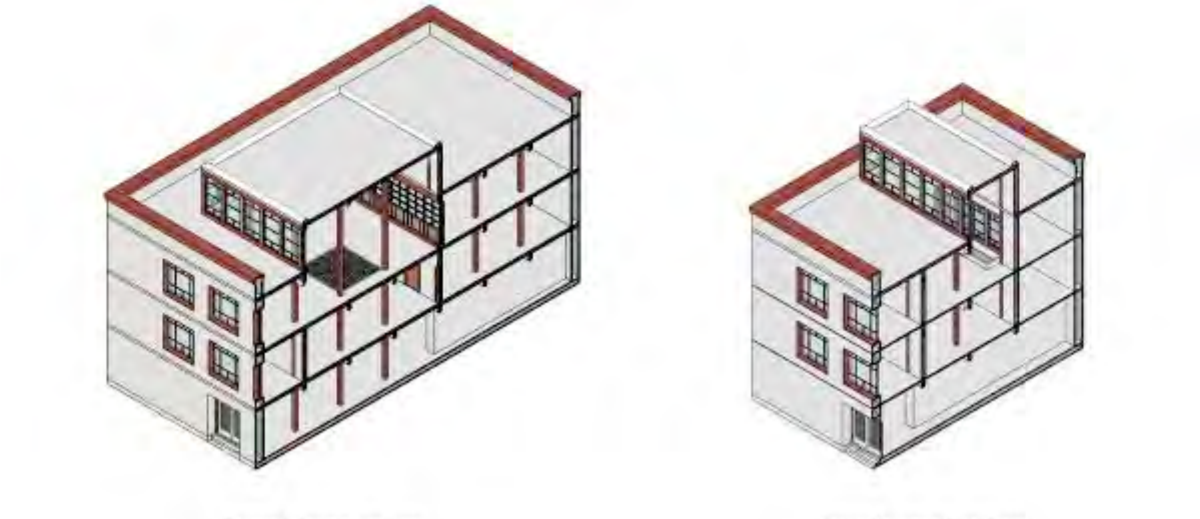

Figure2. Conceptual models of the two forms

The climate control of the archetype

Theoretical analysis

The major characters of Lhasa's climate includes low ambient temperature, high diurnal temperature variations, strong solar irradiance and windy weather, to which this archetype provides complex solutions to respond. Besides general measures of compact form and fenestration of few openings on the north side to reduce heat loss, the skylight, atriums, the horizontal opening and the entrances to the atriums forms a unique system of natural lighting and ventilation to allow airflow and light to move vertically through the building. By this system, the enclosed atrium with a skylight transforms the open space to enclosed indoor space and reduces the heat exchange with the outdoor air and heat dissipation during night. While solar irradiance is still able to be introduced inside the atrium. Natural ventilation is achieved by the way of stack effect instead of cross ventilation and avoids heat loss under windy climate. Compared with open courtyard or patio, this system provides a solution for multiple-storey buildings with large depth and width against cold and windy climate.

The skylight in this archetype has full opening to the south and also remains fully or partially open on the east and west orientation, while the north side is generally closed with solid wall. This fenestration introduces as much solar heat gain and natural lighting as possible into the indoor space. Thus the atrium on the top floor acts as a sunspace, to which the northern rooms can have side windows open for natural lighting and ventilation if necessary. The towering skylight also functions as a chimney and benefits the buoyancy natural ventilation since cross ventilation could be unavailable in the space of large depth. For the lower floor, an area of perforated floor was further employed to allow airflow and lighting through and the lower enclosed space could also benefit from natural lighting and ventilation by stack-effect. Figure3.illustrates the conceptual diagram of environment control for the case of the building in the Jokhang Temple.

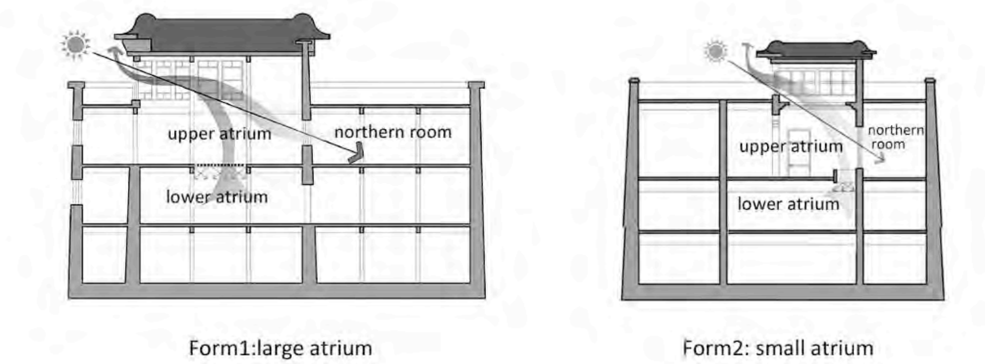

Figure3. Diagram of the two forms

Method of computer simulation

Computer simulations are further conducted to explore the above theoretical analysis. A widely used simulation tool Designbuilder was used for both natural lighting and CFD analysis. Three locations, namely the top, lower atrium and the northern room are selected for evaluation of natural lighting. As the atriums are for circulation and the northern room for office work, according to the Standard for Daylighting Design of Buildings (GB50033), the corresponding daylight factor (DF) and illuminance is required to be above values of 1 and 3, and 75Lux and 450Lux respectively in the condition of CIE overcast sky. The metric of daylight autonomy (DA) is also applied to measure the temporal and spatial distribution of the illuminance over a period of a year in the condition of real climate. As for the evaluation of natural ventilation, the status of airflow at 12:00PM on December 22nd will be simulated to explore the air velocity and airflow direction in this archetype on a typical winter day. The simulation mode is set to natural ventilation and no heating/cooling, the air change rate is set as 1 ac/h, and the other boundary conditions including air temperature, surface temperature, airflow in and airflow out are simulated in advance based on Lhasa' weather data sourced from the China standard weather date.

Results of computer simulation

The simulation results of natural lighting are displayed in Figure 4a and 4b. In Form1 of the large atrium, it can be seen that 49.6% of the area has the DF value over 1, and the DA shows that 90.1% of the area meets the requirement of illuminance for two third of a year. For the lower atrium, only 1.63% area has the required DF value, but 17.2% of the area has the required illuminance for half of a year. As for the northern room with a side window, 10.5% of the area meets the DF requirement, while only 0.77% of the area has adequate illuminance for half of a year. As for Form2 of the small atrium, in the upper atrium, 52.5% area has the DF over the value of 1, while DA value shows that 99.1% of the area meets the requirement of illuminance for half of a year. For the lower atrium, the highest value of DF is 0.63 and no area can meet the requirement of DF. However, DA value shows that nearly 10% area underneath the perforated floor meets the requirement of illuminance for more than half of a year. As for the northern room, 33.5% area meets the requirement of DF, and only 5.5% area has the DA over 50%.

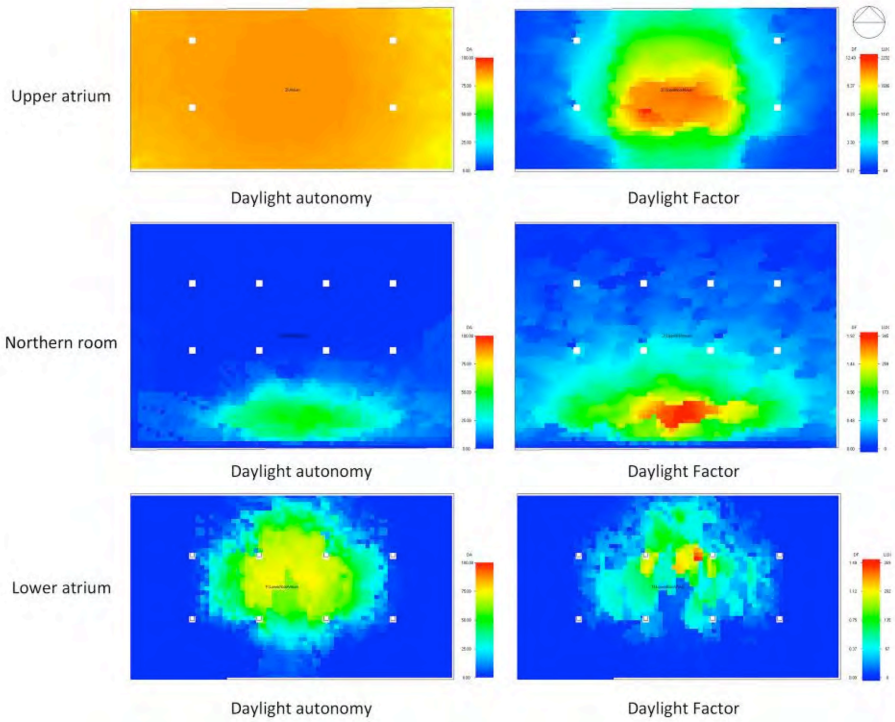

Figure4a. Natural lighting in Form 1:large atrium

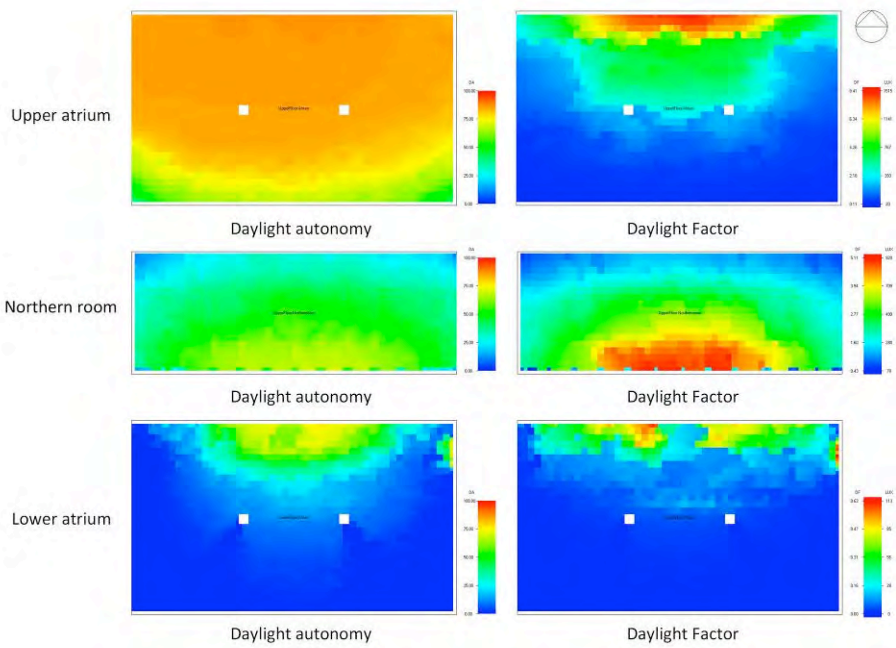

Figure4b. Natural lighting in Form2: small atrium

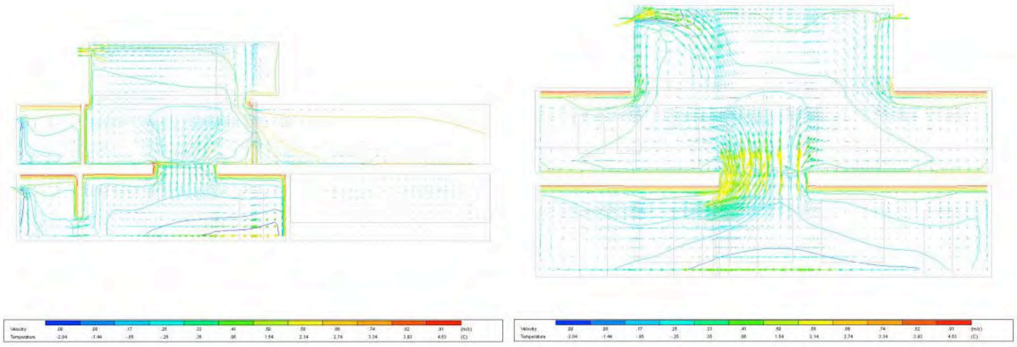
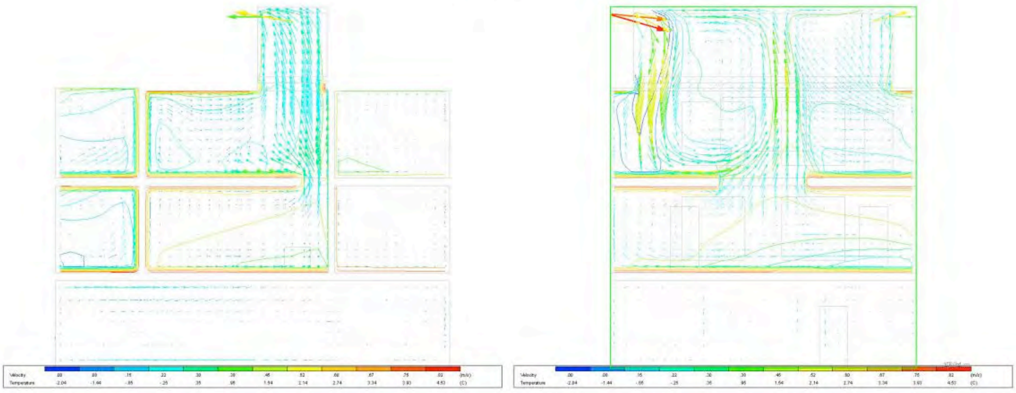
The status of airflow at 12:00PM on December 22nd are illustrated in Figure 5, in which obvious bottom-up airflow through the horizontal opening can be found in both Forms. and the southern and eastern opening of the skylight are the export for the airflow by buoyancy, and the velocity is between 0.25 to 0.4m/s and can be sensible by human body. Cross airflow is also found between the western and eastern openings of the skylight in the two forms.



Form1:large atrium



Form2:small atrium

Figure5. Airflow in the two forms

Conclusion and discussions

The archetype of Tibetan Monastery forms a system to control indoor environment. The second floor is the primary space in this building, for which the skylight and the first floor play the role of transition space.The result of airflow simulation indicates that the natural ventilation by stack effect can be obviously achieved through the system, while the cold outside airflow in from the entrance was warmed up in the first floor before entering the upper floor. The result also suggests that cross ventilation is unavailable in this archetype. In terms of natural lighting, the upper atriums in both forms have sufficient illuminance for most of the time. The northern room on the top floor can also benefit from direct natural lighting for a certain degree, but depends on the the depth of the skylight, namely the horizontal distance between the side window of the north room and the south opening of the skylight. Despite an enclosed space, the lower atriums also obtain certain amount of illuminance by lighting through the horizontal opening. Compared with courtyard or patio, the system finds a solution responding to local climate, which provides natural ventilation and lighting while reducing the amount of building envelope open to the outside space.

PLEA 2017 EDINBURGH
Design to Thrive

To evaluate the environmental performance in Vernacular settlements of Kerala

Ameena Junaize[1], Sujata Karve[2] and Namrata Dhamankar[3]

[1] Department of Environmental Architecture, Dr. Bhanuben Nanavati College of Architecture for women, Pune, India, ameejunaize@gmail.com
[2] Head of Department of Environmental Architecture, Dr. Bhanuben Nanavati College of Architecture for women, Pune, India, sujatakarve@gmail.com

Abstract: Vernacular settlements evolved around the world with a sensitivity towards climate apart from their ethnicity and socio cultural dimensions. This paper will aim to study the varying environmental performance of three vernacular settlements in varying topographical regions in the warm humid climate zone of Kerala, India on the basis of thermal performance. The flexibility of vernacular settlements produces variety not compliant with generalization. The research thus studies whether the contextual difference in these settlements affect the thermal performance of their built environments in the same climate type of warm and humid. The proposed methodology examines the environmental parameters that have affected the building level. For a thorough understanding of the same on site validation and systematic quantitative analysis is carried out. The research methodology has evaluated the said terms on thermal comfort of occupants and socio-cultural precinct as well. The questionnaire survey recorded the thermal sensation of the occupants and a comparison between the typologies was done. The results of the study shows that the parameters of climate vary in spite of topographical variations and cultural difference in spatial planning. It thus identifies the lessons learned from vernacular settlements that could be applicable in contemporary new age community planning as well.

Keywords: Vernacular, Thermal comfort, Climate, Socio-cultural, settlements

Introduction

The vernacular settlement can be interpreted as a pragmatic response to how territorial interventions, on a community scale, are directly conditioned by its geographical features. The settlement is developed in specific models according to its particular climate, geomorphology, geology and available resources, which are materialized through formal solutions adapted to specific socio-cultural perspectives (Guillaud et al., 2014). Climate has a major effect on the performance of the building and its energy consumption. Reducing energy consumption, using natural resources and providing comfortable, healthier and sustainable living spaces are the aims of a climatically responsive sustainable building design (Holmes and Hacker, 2007). Vernacular built form based on building traditions are ecologically fit and may have a sound source of information. A need for place dependent sustainable architecture has to be formulated (Eyüce, 2007). The environmental design features that have been incorporated in the design of the vernacular buildings vary from their location in the plains to that in the mountainous areas in order to adapt to the local climatic conditions. Variations of local climate, depending on altitude and proximity to the sea, have created a variety of bioclimatic design solutions which are specifically adapted to vernacular rural dwellings of specific regions. A number of various functions of the dwelling which have had to meet different comfort requirements have led to the division of internal dwelling spaces into multiple thermal zones offering thermal diversity in the traditional house. (Philokyprou Maria et al., 2014)

This research aims to arrive at a more comprehensive overview of the thermal performance and comfort of Vernacular settlements in Kerala. For this three settlements of varying context and physiographical location were studied. The research studied whether the contextual difference in these settlements affect the thermal performance of their built environments in the same climate type of warm and humid. The objective of the study is to analyse the spatial characteristics of these settlement and evaluate the performance of the vernacular structures in terms of thermal performance of indoor areas. The paper also studied the socio cultural precinct of these settlements.

Description of study area

Kerala state lies on the south western coastal region of the country between latitude 80 17’ and 120 47’ N and longitude 740 52’ and 770 24’ E. It is spread over an area of 38863 sq. km or about 1.2% of geographical area of India. Physiographically, the state can be divided into coastal, midland and highland zones as seen in Figure 1. Rainfall varies from 1520mm to 4075mm and the temperature ranges from 19.80 °C to 36.70 °C.

From the physiographic division of Kerala as seen in Figure 1, a vernacular settlements from each region were chosen as study areas from the assessment of thermal comfort and sociocultural evolution. The settlements chosen for study are typology: 1 (coastal settlement-Calicut), Typology: 2 (Settlement on the plains- Palakkad), Typology: 3 (Highland settlement-Wayanad).

Research Methodology

The research methodology is a case study based method. This study examines how the environmental parameters and topography influenced the interior thermal comfort in three vernacular settlements of Kerala. The proposed research methodology is based on a quantitative and qualitative assessment of the built fabric at the chosen samples. The qualitative investigation concerns with the study and documentation of the three samples for thermal performance. Field work was undertaken to evaluate the thermal performance of 3 typical samples of single storey habitats from the settlements chosen. For the said purpose, the research is carried out with two major aspects - Thermal performance and Socio cultural aspect.

To investigate the thermal performance, thermal comfort of occupants and their opinions which are theoretical and practical investigations will be carried out. Theoretical investigations comprises of literature on comfort models and predicting comfort temperature (ASHRAE etc.) , thermal comfort and its relationship to outdoor temperature etc. Practical investigations include the study of climatic Parameters (outdoor temperature, indoor air temperature, humidity, and air speed) at intervals using meters (5 in 1 meters) and compare the values with ASHRAE standards of indoor thermal comfort. The spaces considered for experimental investigation are the semi open space (Veranda), courtyard, living room and the bed room. These spaces were selected since all the activities happen around these areas from morning to evening and 90% of the household activities happen around these spaces also the spaces are active throughout the day. The data from various areas were taken at a height of 1m from the ground at morning and afternoon for a week, with the windows kept open for unobstructed air flow through the courtyard. The artificial means of ventilation like fans were kept off and un-operated till the experiment was over. A questionnaire survey based on ASHRAE scale of thermal comfort, preference and acceptance is carried out. According to ASHRAE Standard 55-2013, thermal comfort is defined as “the condition of mind that expresses satisfaction with the thermal environment”. Comfort may also be defined as the sensation of complete physical and mental well-being of a person within a built environment. The comfort conditions of the individuals depend on various physiological and environmental parameters. Study of thermal comfort standards suggests that most people are comfortable in the temperature range between 18°C and 30°C, with air-velocity 0–2 m/sec and relative humidity conditions between 30% and 70%, mentioned as ‘comfort zone’ on the psychometric charts. (Ashrae,2013).

The spatial organization and the impact of culture and tradition on spatial design and flexibility, are the major aspects to be considered for ensuring the quality of life. (Priya et al., 2012). Spatial configuration is a technical term that refers to the particular way in which a set of spaces are connected to one another as a network. Semi-structured interviews with residents, local experts (design professionals, local authorities, architects, builders, and locals) have been carried out.

Observations and findings

Comparative analysis

Field measurements were taken for selected samples from mid-January to February 2017.The comparison between outdoor and indoor temperatures and relative humidity from Figure 5 reveals that typology 1 maintains an average difference of 3- 4 °C temperature change, typology 2 maintains 2- 3 °C temperature change and typology 3 which is the high lands habitat maintains a temperature difference of 4-5 °C. This was due to the materials used for construction like mud wall, and thatched roof system.

From Figure 5 we can see that the morning temperatures are within the ASHRAE standard of indoor comfortable temperature of below 30°C for typology 2 and 3. Typology 1 has most of the spaces above 30°C.The relative humidity variation was found to be minimum in the typology 1 settlement even though the wind speed were higher in the range of 0 - 2.6m/s which is due to the presence of courtyards and large openings on all sides. Most of the spaces had wind speed more than the comfortable range of wind speed by ASHRAE standards. The relative humidity in typology 3 was observed to be in the range of below 30% that is lesser than the comfortable range by ASHRAE standards. Hence the use of mechanical ventilation was observed. The relative humidity at typology 3 was observed to have variation diurnal variations of 20-30% between mornings and afternoons, and in turn had wind speed within comfortable ranges of ASHRAE standards (below 2m/s) as shown in Figure 5C.

Thermal performance of different spaces between the settlements

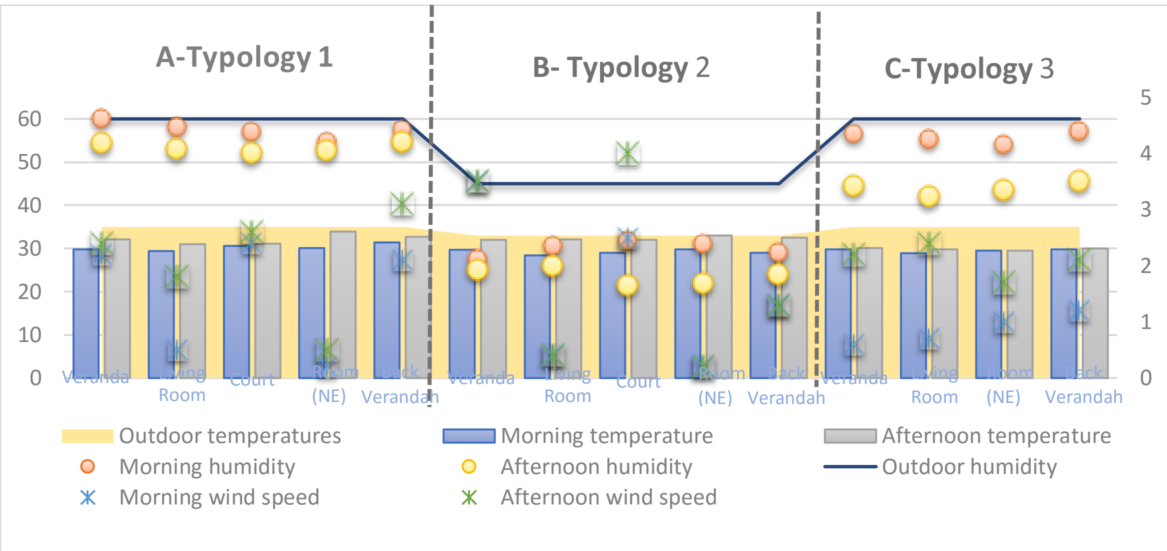

Figure 5. A, B, C, shows the weekly average Temperature humidity and wind speed and outdoor temperature, humidity recorded (*Source – Author*)

The weekly average of the maximum and minimum temperatures in Figure 6 of different spaces across the typologies like Verandah, living room and back verandah shows that the maximum and minimum temperatures are in the range of 29 to 32 °C typology 1. In typology 2 has the lowest temperatures indoor temperatures of 27-28 °C as compared to others. In typology Diurnal Variations in the range of 3-4 °C can be observed. The Diurnal variations between minimum and maximum temperatures of 1 °C is observed in typology 3. From this comparison it has been observed that the Typology 3 settlement complies with ASHRAE standard of maintaining temperature below 30 °C. Typology 2 shows lowest temperatures mainly due to the linear row house arrangement and higher air flow as most of the habitats were oriented linearly in the windward direction. The presence of courtyard helps in maintaining min and max temperatures due to the air flow.

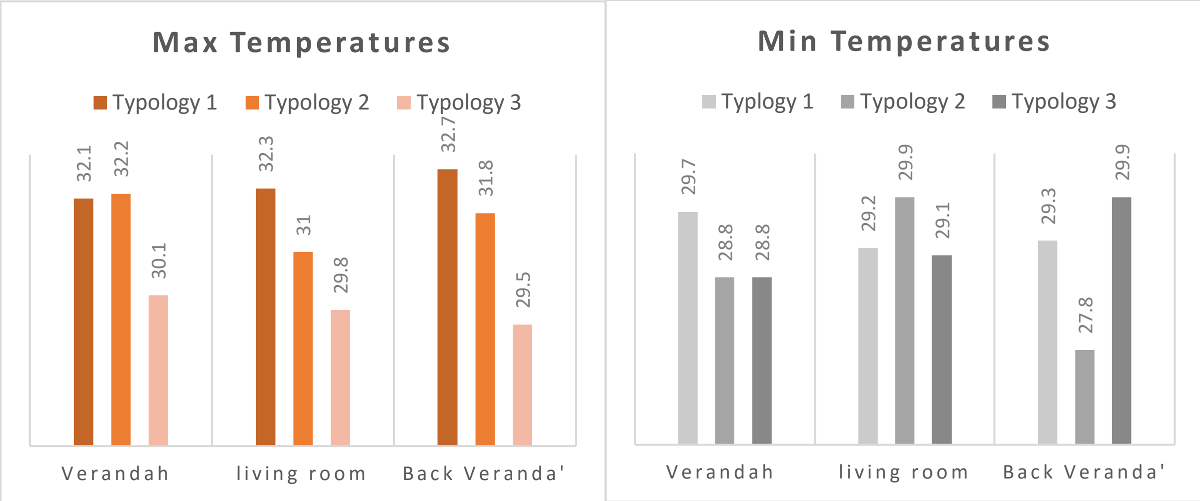

Figure 6. shows the thermal perception of human with respect to the thermal sensation, feeling of comfort, satisfactory level of comfort in the three places. (Source –Author)

Socio Cultural Analysis

Based on the interviews, one of the main considerations for different architectural types is the issue of privacy provision and public-private territories.

In typology 1 the main assessment is the privacy provision and public-private territories. Being a matrilineal society the spatial configuration gives importance to spaces used by women and that occupies majority of the plan. The spaces such as verandas were originated as buffer spaces for women between public interactions of the male members of the habitats. The spatial configuration of the courtyard lies in the women's quarters of the habitat and hence forms a major area for informal interactions amongst women.

In typology 2 social and cultural interactions were seen by the varying use of the veranda space. This settlement of row houses is a temple town and the veranda space was originated as shading area for devotes during processions there by forming a cultural impact of the space .The courtyard originated mainly for rainwater drainage between sloping roofs in the compact row house arrangement. The social status of a habitat can also be observed by the presence of granary which in the olden days were used to store agricultural produce.

In typology 3 spatial configuration division or public-private division has not been seen in these settlement.

Questionnaire Survey Analysis

Questionnaire survey based on ASHRAE scale of thermal comfort, preference was carried out on 75 persons who are inhabitants from each of the three settlements out of which 46 were female and 29 were male and the results were evaluated. It asked participants about the direct sensation of indoor thermal environment in terms of temperature, humidity, air movement and overall thermal comfort. There was no estimation calculation method applied in this case study.

More than 70% of the occupants in all the three settlements mentioned the temperature as not acceptable. The majority of the 30% occupants who said the temperature was tolerable was from the highland settlement typology 3.

The Figure 7 shows the direct sensation of thermal environment in terms of thermal sensation, feeling of comfort, humidity and air speed. Figure 7A shows that the 40% of typology 3 occupants felt slightly cool irrespective of the outdoor temperature and 30 % of typology 1 occupants felt slightly warm due to the higher air temperatures. Most of all 45-50% of occupants from all settlements felt the thermal sensation at the moment was neutral. The Figure 7B shows that the 50% of the occupants of typology 3 are comfortable and 50% occupants of typology 1 are comfortable warm.

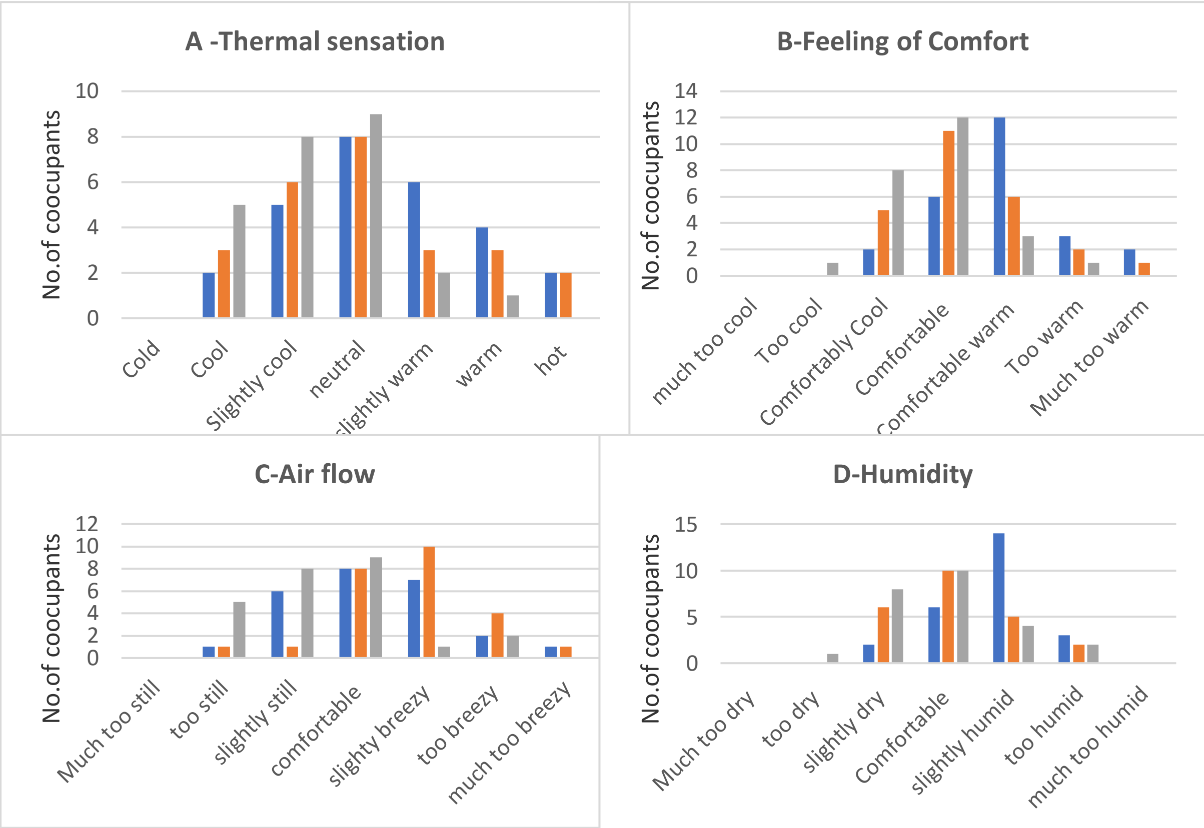

Figure 7. Shows the thermal perception of human with respect to the thermal sensation, feeling of comfort, satisfactory level of comfort in the three places. (*Source –Author*)

Discussions

It can be concluded from the quantitative analysis based on physical reading and qualitative analysis based on questionnaire surveys for thermal performance that the typology 3 settlements is more thermally comfortable to occupants. This can be mainly due to the use of materials like mud walls, thatched roof that helps in thermal insulation. The assumption for significant temperature difference between inside and outside temperatures of all three traditional habitats even during the highest outdoor temperatures is because of the evaporative cooling phenomena that takes place in mud and mud mortar based traditional houses in the case of typology 3 and the presence of passive cooling strategies of courtyards and verandas in the case of typology 1 and 2. The thermal environment in terms of humidity and air speed can be seen to have been modified in typology 1 and 2 due to the presence of courtyards .It can be also noticed that the diurnal variation between morning and afternoon indoor temperature is the highest in typology 3 .This can be attributed to the higher altitudes this settlement is located in.

Furthermore the study on social and physical aspects of the settlements reveal that the spaces originated for social interaction and public private buffers such verandas and courtyards act as major climate modifiers. Typology 1 and 2 habitats there is a difference of 2°C to 3°C in the spaces adjacent to the verandas ,i.e. the living room. An explanation to this result can be the buffer a wide veranda provides from the low angle sun. This point has also been confirmed by the onsite temperature measurements. Courtyards which were observed as spaces for social interactions may have thrived due to the maximized air velocities it provides in the spaces surrounding it.

Hence the typological variation in its spatial configurations according socio-cultural precinct does show a considerable difference in the indoor comfort parameters as separate entities. In typology 1 the large bungalows have a spatial configuration that allows maximum ventilation which is a criteria for the coastal habitats, typology 2 shows that the narrow row houses with only two openings have their orientation in such way for maximum ventilation punctured by courtyards, typology 3 has the optimum thermal performance by the use compact planning and traditional materials.

Local Indigenous Practice of Traditional Community in Implementing Green Concept on Low Cost Housing Construction

Dewi Larasati ZR, Suhendri, Anjar Primasetra, Yuni Sri Wahyuni, Siswanti Zuraida, Sahid Mochtar

Abstract: As a developing country, and the 4th most populous country in the world, Indonesia still lacks of housing. Thus, mass rapid construction method is needed in housing construction in Indonesia. However, this massive housing development could lead to destructive effects on environment. It is important to make the housing development follows green concepts in the execution. Local indigenous of traditional community is acknowledged as one of the sustainable ways to build. The traditional method is known for its small environmental impact. This paper discusses the sustainable house construction method of Kampong Naga community, one of the remaining traditional villages in Indonesia. Field observation and interviews to the stakeholders of Kampong Naga were done during the research. The result shows that Kampong Naga has implemented some of green concepts in their traditional construction method, which has been inherited since hundreds of years ago. The villager is efficient in material use, also wise in site-planning, effective in building design, and even in the construction process. This paper focuses on local indigenous practice in building construction materials. Quantitative analysis was conducted on the use of sustainable materials by local communities with a life-cycle analysis approach to see the value of embodied energy and the environmental impact. Then a comparative study of embodied energy values and environmental impact between traditional houses and modern community homes was carried out. The result is expected to be an initial endorsement for the strategies of green concepts implementation in modern context.

Keywords: green building, local indigenous, low-cost housing, passive design, sustainable material

Introduction

Sustainable development has been introduced to Indonesia since three decades ago. However, the term is not implemented well in the country, and thus environmental destruction in Indonesia still at a high rate. Construction industry, particularly housing industry, is still the main contributor to energy consumption. It is well known that the most massive energy usage comes from air conditioning. Along with its energy consumption, construction industry also emits a huge amount of carbon dioxide (US EIA, 2012).

There are some efforts already done, either by Indonesian Government and the society, in promoting environmentally sound development. One community that is recognised for their practice in sustainable development is Kampong Naga. Kampong Naga is one of the traditional villages, located in Neglasari Village, Salawu District, Tasikmalaya Regency. Kampong Naga's people have implemented principles of green construction for years, as old as the village. The principles of green building implemented such as climate responsive design, utilisation of local materials, and passive solar architecture (Yeang, 2006).

This paper elaborates principles of green building concept in local indigenous practice of house construction in Kampong Naga. The green concept is considered since site planning to building design, as well as in the building construction. First discussion of the paper includes *genius loci* in site planning, materials selection, indoor air quality, daylighting, and construction process. Then, the paper focuses on the utilisation of sustainable materials by Kampong Naga's people. Lessons from the traditional values are beneficial for modern society in order to applying sustainable concepts in modern building.

Methodology

This research is conducted in three phases as follows:

1. In-depth study to construction techniques in the houses. This is done by exploratory case studies, to obtain good understanding of the general characteristics of house design and construction process in Kampong Naga.
2. Field observation and interview with the local community, especially the construction workers in the village. The observation focuses on traditional preservation techniques for bamboo, that usually used by people in Kampong Naga. The existing preservation techniques are then analysed quantitatively by using Lifecycle Cost Analysis. Analysis of the techniques specific for its environmental impact, particularly the effect of waste resulted from the bamboo preservation process.
3. Calculation of embodied energy materials of Kampong Naga's traditional houses. Embodied energy calculation for the traditional house is developed from Construction-Works Unit Cost Analysis (AHSP) published by Indonesian National Standard (SNI). Each work item on construction work has AHSP from the SNI. The AHSP consists of three components: material, labour, and equipment. By extracting material component from the AHSP, a detailed material usage of a building component can be obtained. Then, by referring to inventory data of material's embodied energy, the sum of material's embodied energy of Kampong Naga traditional house can be calculated.

Local Indigenous in Implementation of Green Concepts by Kampong Naga

Green concepts practiced by people of Kampong Naga include: 1) appropriate site development and water conservation in the village; 2) sustainable materials with low embodied energy; 3) low carbon emission in building operation with good daylighting and ventilation strategies; 4) local construction technique and labours, which is environmentally sound and prefabrication technique.

People of Kampong Naga are really strict to their site regulation. They have a clear mandatory site planning rules (Figure 1). Development of Kampong Naga is planned to three parts, such as:

1. Developed area, consists of housing area, service area, public buildings and public space, and place of worship;
2. Green area, consists of the village's including consumption forest used for daily needs, production forest used for economic activities, and sacred forest that is conserved;
3. Water conservation area, consists of fresh water conservation area for drinking and cooking, fishpond area, bamboo preservation pond, and waste water management area.

Figure 1. Site plan Traditional Community of Kampong Naga (source: Utami, 2014)

The developed area covers houses that are organised in form and location. The houses are rectangular in plan and built as stilt houses which are elevated 50-60 cm from the ground. They are commonly built as detached houses. There are also religious building, public space, and public building such as public toilet and granaries in the area.

Figure 2. Kampong Naga, Salawu, Tasikmalaya, West Java, Source: http://id.wikipedia.org/wiki/Kampong_Naga

Another part of the village, the forest, covers production forest, consumption forest, and sacred forest. The sacred forest has a holy significance for the people of Kampong Naga. It gives a spiritual and psychological effect to whose violate the prohibition of the forest. The forest is located at the near side of the village and surrounded by Ciwulan River as its boundary. The river helps to protect the forest from deforestation. Due to conservation of the forest, Kampong Naga always has natural fresh water storage in their village. It can fulfil the village's water needs for fresh water. Moreover, production area can be planted as paddy field, or farmland. It is located at the west and east side of the developed area. Another production tool is *sung lisung*, which is a building that used by the people for rice pounding.

Kampong Naga house is a stilt house that enables air movement below it. Massing of the houses is oriented in a north-south axis. Hence, the most radiated area in the east and west side of the building, only received solar radiation in a shorter time. Solar radiation is also blocked by wide roof overhang. This design strategy creates more pleasant indoor air quality. Further, the house layout drives cross-ventilation across the building. Besides, wall material that made of bamboo makes a kind of porous building that can deliver fresh air into the building (Figure 3).

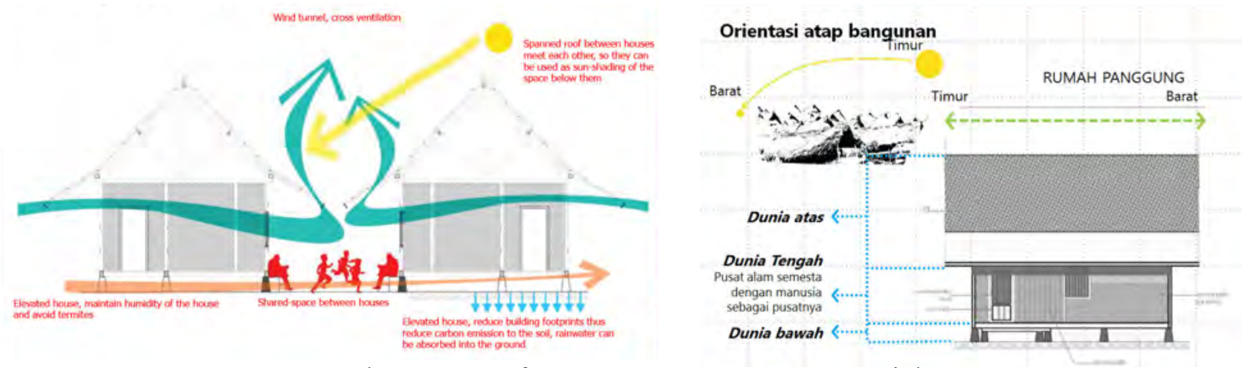

Figure 3. Implementation of Green Concept in Kampong Naga's house

The porous wall and openings also enable daylighting to occur in the house. Another design feature that brings daylight into the house is a chimney in the kitchen area. Beside its function as a channel for smoke from the kitchen to the outside, it also creates daylighting (Figure 4).

Figure 4. The use of day lighting in chimney, woven wall, and openings in Kampoong Naga Local House

Sustainable Material in Housing Construction

Houses in Kampong Naga cover 30-60m^2 area. They use naturally brow materials such as wood, bamboo, fibre or coir, and tepus leaves. Beside its availability in the village, the materials are also strong and durable. All of the houses are stilt house with Sundanese style (Utami et. al., 2014). The roof is design with traditional style called *julang ngapak*, with raised floor and pedestals and its column. The design has a philosophical meaning for the people, which combine environmental, economic, social, and cultural value.

The houses' roof material is coir or coconut fibre, and sometimes dried palm frond. The walls are made of bamboo, with wooden column, and stone foundation. Figure 3 displays bamboo material use in Kampong Naga's houses.

Kampong Naga exploits natural material such as bamboo and timber as building components. Based on the observation of some of the indigenous construction of the Kampong Naga is including:

1. The use of bamboo as a sustainable material. Bamboo is a material with a very short harvest period
2. A technique to increase the life span of bamboo, through the harvesting process, the process of preservation and storage
3. Use of the green building concepts in the arrangement of buildings and the construction of residential units
4. The application of the concept of local prefabricated, in improving the quality and the acceleration of the development process

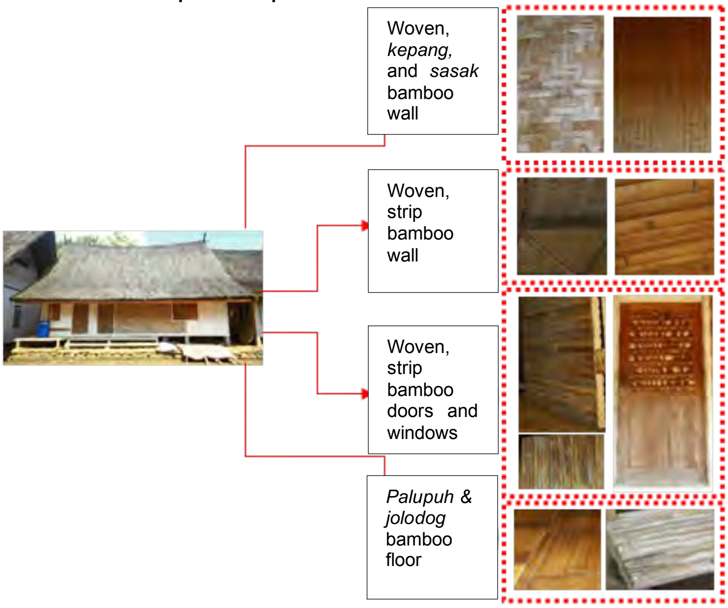

Figure 5. The use of bamboo material in some elements of Kampong Naga's house

In terms of Bamboo preservation method, the villagers also used traditional inherited methods such as a submersion in the preservation pool and coating technique with camphor (Zuraida, et al., 2015). Kampong Naga's bamboo preservation technique is considered as environmentally sound method. Table below comprises some bamboo preservation techniques that usually used in Kampong Naga.

Table 1. Characteristic of Bamboo preservation technique in Kampong Naga

Preservation strategy	Preservation technique
Harvesting	• Bamboo that is cut to be used in building construction is a minimum three years old Bamboo. • Bamboo cutting can be done anytime except at the full moon, Tuesday and Wednesday, because bamboo is not in good condition to harvest at those time. • It is better to cut bamboo at 11 am to 15 pm, or after midnight to the dawn, because Bamboo is not growing at those times.
Preservation	• Submersing the bamboo into a muddy pool for 1 to 3 months. This process is aimed at closing the pores of the bamboo in order to protect bamboo from insects. • Drying the bamboo below a shaded place for 3 to 7 days. • Covering the bamboo with calcium hydroxide solution to protect the bamboo from climate condition and close the pores. • Some bamboos are also painted.

Bamboo preservation technique by Kampong Naga's people is an environmental friendly process compared to modern preservation technique. This is implied by Table 2 below. The table shows comparison of environmental impact of different bamboo preservation techniques.

Table 2. Environmental impact of bamboo preservation techniques

Preservation techniques	Environmental Impact		
	Human Health	Eco Toxicity	Resource Depletion
I. Traditional			
Submersion in a muddy pool	0.00000	0.00000	0.00000
limestone covering	0.00003	0.00002	0.00002
Painting	0.00016	0.00012	0.00016
II. Modern			
Scalding: *borax-boric acid*	0.00003	0.00001	0.00002
Sarpeco 8 injection	0.00069	0.00031	0.00065
VSD; *Borax- Baric Acid*	0.00191	0.00070	0.00123
Submersion in salt solution	0.00601	0.00281	0.00576
Filling with lubricant and oil	0.00726	0.00419	0.02531
Submersion in camphor and detergent	0.05042	0.02308	0.09670

Embodied Energy (EE) of Material Usage in Housing Construction

Total energy consumed by construction materials from its production to post-construction stage can be divided to embodied energy and operational energy. The amount of energy used in the process is considerably huge. This huge amount of energy clearly affects the environment. The environmental effect can be measured by using the total energy that is used in the whole construction life cycle. One of the indicators is embodied energy (Treloar, 1997; Dixit, 2013).

Calculation of Kampung Naga's traditional house are conducted for three type of house area: Type 21 m^2. Type 36 m^2, Type 45 m^2. These types are the common low-cost housing scheme constructed in Indonesia. The embodied energy calculation results of the three house types can be compared to embodied energy of modern low-cost house types the process is summarised by Figure 6.

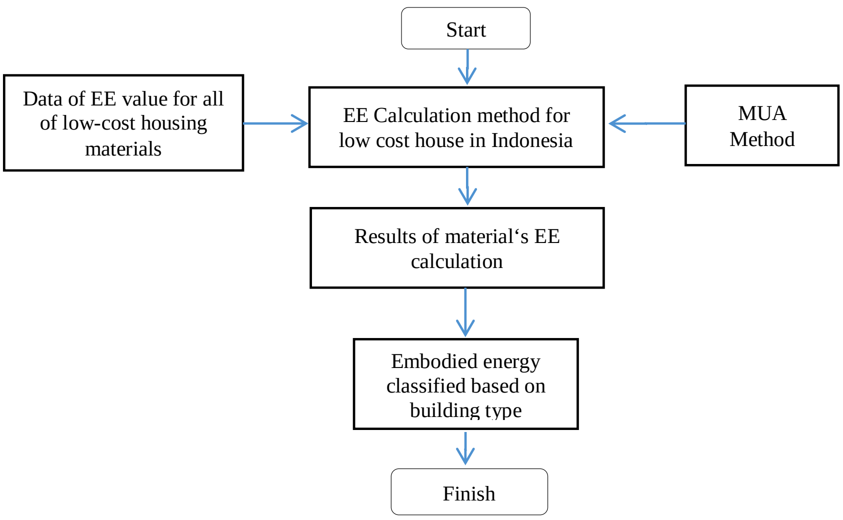

Figure 6. Calculation of material's embodied energy value used in this study (Yuni, et. al., 2015)

Table 3 below show the embodied energy calculation results. It compares embodied energy of Kampong Naga and modern low cost house.

Table 3. Comparison between EE values

No	Building Component	Embodied Energy (%) of Unit Types of Modern House			Embodied Energy (%) of Unit Types of Kampong Naga House		
		21 M^2	36 M^2	45 M^2	21 M^2	36 M^2	45 M^2
1	Site works	0,80	1,62	2,17	0,40	0,90	1,18
2	Foundation	10,81	14,43	21,25	7,18	32,91	26,38
3	Wall	52,79	55,20	65,72	7,97	14,62	20,43
4	Roof	58,06	69,73	89,30	3,66	3,66	4,39
5	Floor	0,59	0,65	0,86	0,00	0,21	0,25
6	Building Services	3,88	3,88	5,28	7,13	0,00	0,00
	TOTAL	126,93	145,51	184,59	26,34	52,30	52,63

Based on materials used in modern low cost house and Kampong Naga house, it can be seen that EE value of the Kampong Naga house is much lower than the modern house. This indicates that energy consumption in the whole life cycle of Kampong Naga house are much smaller. Thus, its environmental impact is lower.

Sustainable Construction Method

Houses in Kampong Naga are built using traditional prefabrication method. Kampong Naga prefabricated houses are made of bamboo building components prepared in the workshop with a particular standard which is done using a machine or manual, or a combination of both. Prefabricated bamboo products that made is often in the form of cubicle wall of bamboo, *Palupuh*, laminated bamboo, and bamboo sticks. Prefabrication method may accelerate the construction process and shorten the completion time. This can be seen in the observation of time spent by the workers on site, which is lower in the prefabrication building than the conventional one (McGraw- Hill Construction, 2011).

Prefabrication method used in Kampong Naga utilize local workforce in the process. Thus, the traditional techniques with high aesthetic value are preserved and inherited from generation to generation. Traditional technique tends to be more sustainable and have lower environmental impact. The techniques are potential to be used in modern way. Prefabrication level of people in Kampong Naga is surely high, with the componentization system and simple equipment.

Conclusion

Several types of implementation of green concepts have been applied by Kampong Naga's people in the building construction. Results from this study show that indeed the Kampong Naga's practice has a positive impact to environment. Some conclusions that can be written are:

1. Kampong Naga's indigenous practices in construction are in line with the concept of sustainable building, such as sustainable site planning and passive design for thermal and visual comfort.
2. The use of sustainable local materials with environmental friendly preservation technique have less impact to environment, as well as low embodied energy value;
3. Embodied energy of Kampong Naga's traditional house is lower than the conventional low-cost housing. The difference is mostly caused by material selection. Modern low-

cost housing development should consider this, since its conventional low-cost housing need to be more efficient in terms of embodied energy.
4. Beside the material selection, Kampong Naga also implements a sustainable prefabricated construction system. Prefabrication level of people in Kampong Naga is surely high, with the componentization system and simple equipment. It has been developing in the community since hundreds of years ago.

The huichol traditional dwelling and the inhabitant adaptive response

Alicia Delgado López[1], Adolfo Gómez Amador[2], Eugenia María Azevedo Salomao[3] and Jorge Ojeda Sánchez[2]

[1] Autonomus University of Nayarit, Tepic, México, alicia@uan.edu.mx;
[2] Faculty of Architecture, University of Colima, Colima, México, amad@ucol.mx
[3] Faculty of Architecture, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, México

Abstract: The huichol people are recognized as an ancestral culture that still preserves its customs and traditions. They are part of the 62 indigenous groups that inhabit the Mexican territory. Their houses reflect their worldview, consisting of several single space structures arranged concentrically in relation to a campfire. This is located at the center of a sacred courtyard. They are built from natural local materials as stone, adobe and thatch. Their construction techniques as part of accumulated knowledge have been passed on from generation to generation and reflect the close relationship with the natural environment. However, from the need for better climatic conditions they practice seasonal migration to another site of the western Sierra Madre, where they have other series of constructions that are recognized as an extension of their dwellings. The analysis of the climatic condition and the use of the psychometric card shows us that is an adaptive response. This study aims to show a further example of climate response that exposes a passive form of adaptation to the environment as a fundamental reason for human existence in the natural environment.

Keywords: Seasonal migration, migration pattern, huichol dwelling, adaptive response, vernacular architecture

Introduction

The huichol traditional architecture is a remarkable phenomenon because it is a correct architectural and environmental response to the local context and climatic conditions. Coupled with this, the historical context in which it develops, is the trigger for this form of adaptation to the environment. This is a response to the search of the desirable environmental comfort and the daily domestic and social activities.

This analysis is based on the theory of comfort from the perspective of the adaptive approach. From this point of view, thermal comfort is conceived as a mental state in which subjective and objective variables are involved that intervene in the energy balance between the human body and its surroundings through actions that the human being accomplishes to reach it, either, internally through physiological and psychological processes, as well as externally with adaptations to its surrounding environment (Gomez-Azpeitia et all, 2007).

The actions that can be performed to achieve this state of well-being can be grouped into four types: Modifying internal heat generation, modifying the heat loss rate of the human body, modifying the thermal environment, or moving to a different environment (Humphreys, 1981).

In this paper, we observed a huichol group that practice the seasonal migration from a place that is at 882m altitude to another site located at 351m altitude, in the bowels of the western Sierra Madre, in search of better conditions of habitability.

History

The huichol people habits the western Sierra Madre, between limits of Nayarit, Jalisco, Zacatecas and Durango states. The *wixaritaris* as they call themselves, is one of the Mexican original groups that preserves its culture and traditions now a days. The archaeological information has registered its origin since the prehispanic time (Weigand, 1998; Zepeda, 2003). At that time, many populations of huicholes ancestors habited valleys and low areas.

During the European people invasion, the huicholes were confined to the mountains area. Later, the invasion promoted by landowners and half-caste groups forced them to leave their accessible and productive lands. Fleeing from the harassment and mistreatment of the invaders, they managed to establish themselves in the mountains and canyons of the western Sierra Madre where today most of the huichol population habited (Torres, 2000; Neurath, 2002). The rugged topography and its variety of climates contributed to the way inhabitants adapted to these conditions to meet their most pressing needs (Braniff, 2004). Nowadays we can still watch the environment adaptive way for the resources exploitation.

Method

In order to carry out this research, field visits were made to obtain primary information through direct observation, the field trips in rural settlements were a few number of traditional Huichol buildings still exists. The localities which are considerate in the study are Los Encinos and Las Palomas. The field trips involved a detailed photographic record of the buildings stock, as well as an analysis of the typology and the morphology of the dwellings. Furthermore, the architectural survey of houses was made, as well as the registration of materials and construction techniques. All the above-mentioned observations are combined with a bibliographical study of the Huichol traditional architecture during the 19th and the 20th century, as an archaeological registry.

Focusing on the seasonal need for comfort, a comparative study of the winter and summer accommodation in terms of thermal performance was conducted. The environmental adequacy statistical information on climatic conditions from the Meteonorm 6.1.023 program was evaluated and analyzed in the Gomez-Azpeitia bioclimatic chart program. At the same time, the thermal behaviour of the Huichol dwellings was investigated using a computer simulation with the Design Builder 4.7.0.027 program. Measurements in existing houses in order to verify the simulation results were made.

Description of the dwelling

The huichol dwelling is formed by a series of mono-spatial constructions that settle around a campfire located in the center of a courtyard, as the architectural structures are ordered in the ceremonial places. At the same time, they are governed by the principle of the quincunx. The quincunx is a rhomboid cross which lines link with its main place of worship. In this way they set up their territory, their ceremonial centers and their domestic units denominated rancherías (Neurath, 2002; Torres 2000).

Each ranchería is seated in an isolated manner and dispersed around the main ranch belonging to the elder chief, secondary rancherías can belong to the sons or the wives. The domestic unit is made up of the buildings pertaining to the kitchen, parental shrine, barn, rooms, also integrate the orchard, farm, and the coamil. Those are buildings made with the local material such as stone, adobe, wood and thatch, which are characteristic of vernacular architecture. The typology of buildings is varied according to the construction systems and the combination of material used. Generally, the constructions are mono-spatial and the geometry is rectangular, the oldest buildings can be of circular plant or circular later walls (Lumholtz, 2006, Neurath, 2002; Torres, 2000).

In the example, we can observe that its rooms are built around a courtyard, around the centre of the courtyard we find a bonfire that represents the centre of the quincunx in relation to the place of worship that makes it up. (Figure 1).

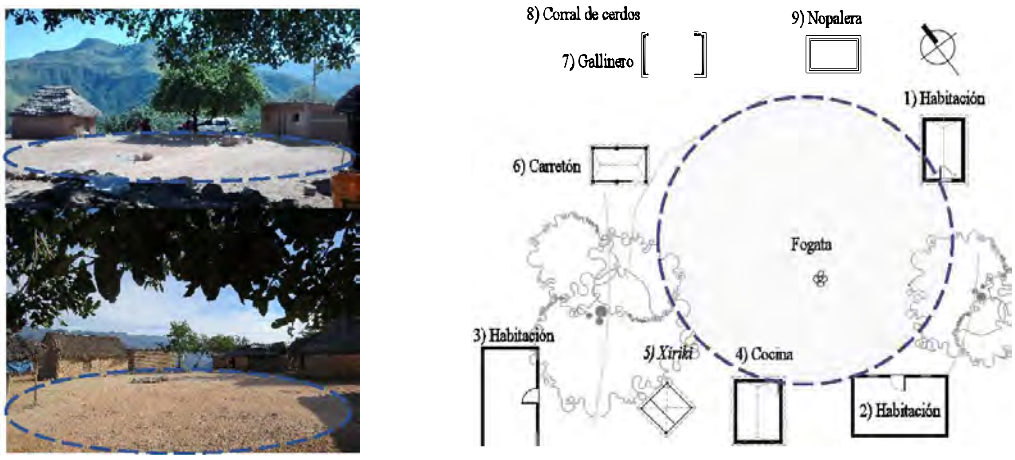

Figure 1. Los Encino´s dwelling.

The family shrine (xiriki) is a mono-spatial construction and it´s placed in the west, facing the central campfire with an east view. This building determines the position of the rest of the rooms. The kitchen is another construction that is located to the west of the courtyard and represents the main building of the ceremonial centre in analogy with the religious space.

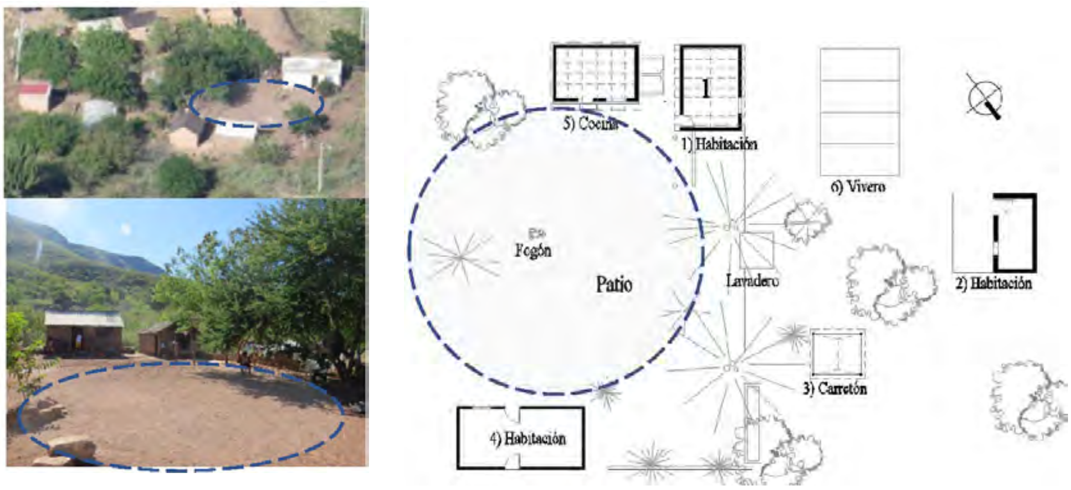

Figure 2. Las Paloma´s dwelling.

The barn (carretón) is also around the courtyard and is made of wood, otate (a kind of smaller bamboo), and thatch, rise from the ground almost a meter, its reed walls placed vertically or horizontally are permeable to the necessary ventilation for the conservation of the corn grain from its harvest. The rest of the buildings are placed around the yard in a scattered way; they are used to spend the night and store their belongings. The vast majority are mono-space rooms and are built with stone walls or adobe and thatch cover. The constructions in Las Palomas have the same characteristics with exception of the cover, it is made of asphalted cardboard instead of thatch and there is not a *xiriki* because this extension does not represent a ceremonial centre (Figure 2).

Los Encinos climate analysis

Los Encinos is a population located in the sierra of Nayarit at 881m altitude (INEGI, 2016) in the highlands we have a sub humid - semi warm climate (García, 1987). In general, the climate of the mountain is moderate during the summer and cold during the winter with 21°C annual average temperature, presenting 30°C as maximum temperature, and 12°C as minimum temperature. The annual precipitation is close to 800mm with a rainy season from June to October, with frequent rainfalls from December to February.

The psychrometric chart applied to these conditions is shown in figure 3 and indicates the requirements or strategies of air conditioning to be in comfort.

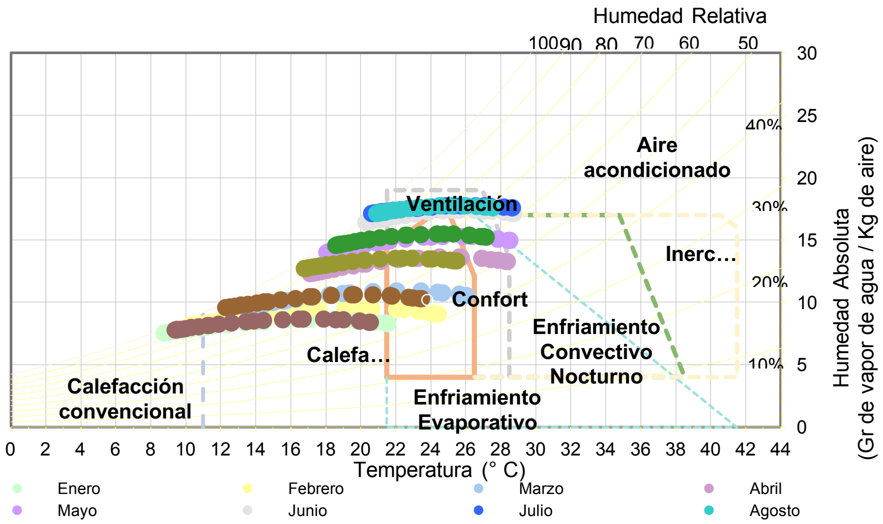

Figure 3. Los Encinos Psychrometric chart.

According to the psychrometric chart, in the period December to February, it is necessary to have an active heating system during the night and part of the early morning. While solar heating as a passive conditioning system is necessary most part of the year. In the months of June to August, the ventilation is important to maintain the comfort zone, only in a short time of the day air conditioning is required. In this part of the mountain a problem would be the conditions of low temperatures during the dawn in the months of December to February but the rest of the year the conditions of temperature that they present allow a state of comfort for its inhabitants.

The Design builder program was used for the simulation of rooms 1 and 2 with interior temperature conditions (figure 4). The characteristics of the buildings analyzed are shown in Table 1.

Table 2 shows the properties of the materials that were used in the computer simulation.

Room 1 is built with traditional materials. In the typical summer week this room has a similar thermal behaviour to the exterior in the early hours but a lower temperature than the exterior during the day. In winter, room 1 offers temperatures higher than the outside and oscillate between 15°C and 20°C whereas the outside temperatures are between 8°C and 15°C. That indicates the level of environmental adequacy of the building.

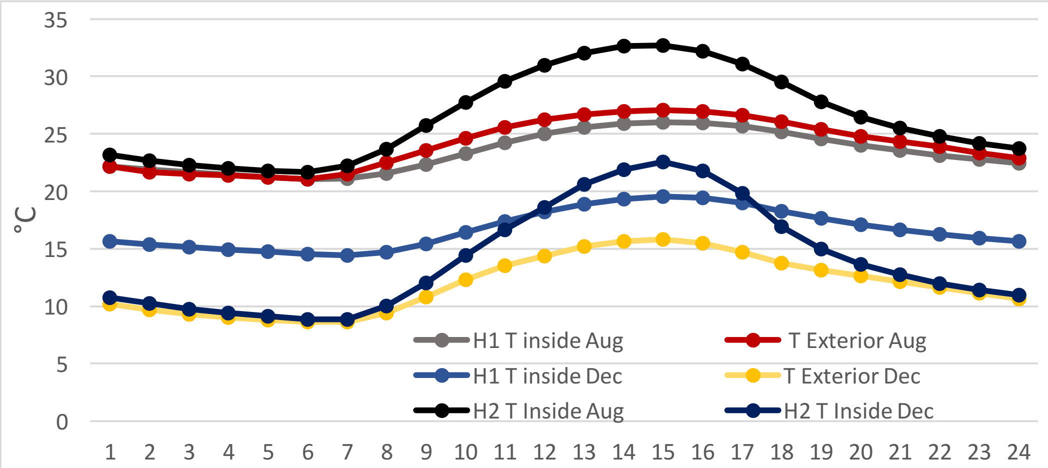

Figure 4. Los Encinos rooms 1 and 2, indoor and outdoor temperature data for a typical summer week from 10 to 16 August and a typical winter week from 22 to 28 December.

Table 1. Physical characteristics of buildings.

Los Encinos	***Dimensiones (m)***	***Materiales***		
	Ancho x largo x h:altura	**Muros**	**Cubierta**	**Piso**
Habitación 1	2.53 x 3.86 x 2.45h	Adobe	Zacate	Tierra
Habitación 2	3.70 x 5.80 x 2.30h	Adobe	Lámina de cartón asfaltado	Tierra
Las Palomas				
Habitación 1	5.43x3.88x3.00 h	Adobe	Lámina de cartón asfaltado	Tierra

Table 2. Thermo physical properties of the materials for the Design Builder program 4.7.0.027

Propiedades de los materiales	***Densida d kg/m3***	***Conductividad w/m°C***	***Calor específico KJ/m3°C***	***Emisividad***	
Adobe	400	0.30	900	0.40	González
Block de jal	1375	0.38	840	0.50	www.CRICYT.ED U.AR
Carrizo	800	0.15	1255	0.90	Elizondo-Mata et.all.,Manuel Martín Monroy
Mortero cemento-arena	1800	1.00	1000	0.90	ISO 10456 DB
Zacate	310	0.057	1300	0.60	BRE
Cartón asfaltado	1100	0.14	1140	0.90	Manual arq. Solar
Concreto	2400	1.80	1050	0.90	Rosales X.

In figure 4 we can observe the simulation of room 2, it is important to notice that it has a variation in the construction materials, its walls are of adobe and the cover is made of asphalted cardboard. During the day this building has a significant solar gain inside the room, temperatures raise from 4 to 7 degrees in the hours of greatest incidence. It is important to emphasize that during the day the inhabitants do the activities outside, in the shade of the trees. During the night the room is occupied to sleep and the interior temperature is similar to the outside with an increase of one degree of difference. This condition of higher temperatures than the exterior is unfavourable for the staying inside this construction, as opposed to the house with thatch cover that decreases the outside temperature during the day. It is interesting to observe that in cold periods, the traditional building offers higher temperature than the exterior, the effect of the heavy weight construction on the internal thermal environment is significant in the annual behaviour. The adobe walls contribute to better conditions because of their high thermal mass.

The migration to the place they call “rancho de secas” at the lower part of the mountain, on the side of the Chapalagana River occurs in October, once the rainy season ends and before the winter season starts. In this time the night temperatures start to decrease and an active heating system is necessary.

Las Paloma’s climate analysis

Las Palomas is located at 351m altitude, in the Chapalagana river canyon, in this place there is a sub-humid warm climate (García, 1987), with an annual average temperature of 25°C, with an average temperature range from 19°C to 36°C; the annual rainfall is about 700mm with a rainy period between June and October with frequent rainfalls in December and January; it has a long and hot period from May to September, with an about of 31°C average temperature (INEGI, 2016).

The psychrometric chart of the site shows that to reach the comfort zone ventilation and solar heating, passive acclimatization strategies are required. In October to April period, passive climatization strategies such as ventilation at day, and solar heating at nights. In April convective night cooling is recommended for a short time, all those are easy actions to obtain (Figure 5). In the period from May to September, the temperature conditions demand the implementation of air conditioning to achieve comfortable conditions in the place especially in the months of June, July, and August. This period occurs also when the seasonal migration to Los Encinos, in the up part of the mountain, takes place.

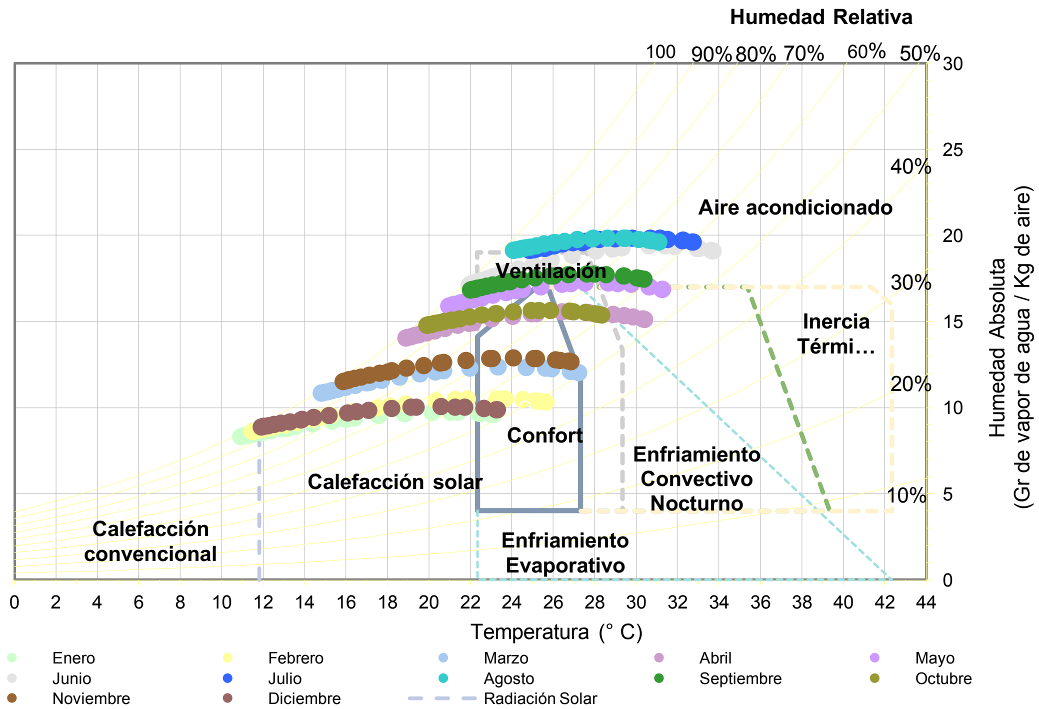

Figure 5. Las Paloma´s psychrometric chart.

In this place the interior temperatures simulation was made for room 1, the table 1 shows the room 1 construction characteristics used in the analysis of the thermal performance. Table 2 shows the thermo physical properties of the materials used for the simulation.

Figure 6 shows the thermal performance of the interior of room 1 in Las Palomas locality. In the simulation of a typical summer week, the temperature inside the room rises above 30°C after one o´clock. When the maximum temperature occurs outside, it does not exceed 30°C. As we can see in the psychrometric chart, these temperatures leave the well-being zone and an active air condition strategy is necessary.

In the months of October to May, when people are in that house, the temperature inside the building is maintained between 20°C and 26°C, it can be pleasant for their occupants and just passive strategies are required such as solar heating.

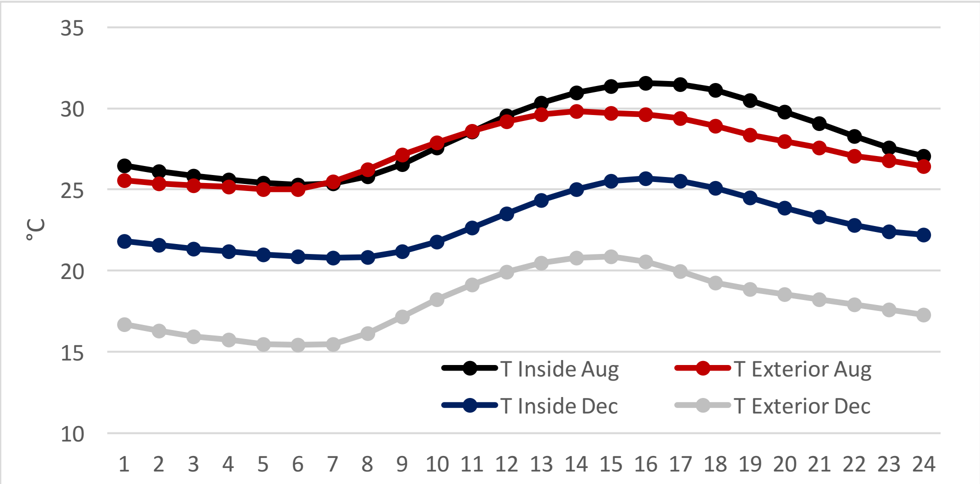

Figure 6. Las Paloma´s room 1 simulated temperature data for a typical summer week from 10 to 16 August and a typical winter week from 22 to 28 December.

Throughout the year the interior temperatures are higher than the outside temperatures, due to the materials with which the room is built. It is also observed that the interior temperature oscillates between 20°C and 25°C during the period of stay, this is a positive behaviour to stay at night, because the exterior temperature in this period is from 15°C to 20°C. The migration to the "Rancho de Aguas" as they call it to the high part of the mountain occurs in May when the maximum temperatures surpasses the line of 30°C and almost reaches 35°C in the month of June.

Winter exterior conditions at the Rancho de secas are more favourable when it is about 15°C to 21°C. Summer exterior conditions at the rancho de aguas are more favorable to stay, when it is about 20°C to 27°C. In the periods with conditions that require an active strategy, according to the psychrometric chart, the migration occurs.

Conclusions

By thermal performance analysed of the huichol dwelling in relation to the occupants´ way of living, we can conclude that by the necessity of better environmental conditions, the huichol dwelling occupants with the available resources, basic knowledge, and accumulated experiences, built their dwellings to stay in comfort throughout the year. What primarily improved their comfort conditions was the division of their house in two distinctive seasonal buildings divided by 550 m of altitude.

The occupants´ priority is to enjoy outside living spaces, where they could practice their communal outdoors activities with a comfortable environment. Therefore, the imigrating pattern is a direct response to this need. The forms of construction executed with simple mono-spatial isolated plants, scattered on the ground, with a single access span give us an account of the open-air life that they develop. The generous space at the center of the buildings indicates that there is an activity that accommodates many people, and it is directly related with their worldview. This also shows the relationship of the individual with his environment and the dominance of the rugged topography for the satisfaction of his needs.

Contrary to the data obtained in this analysis, traditional architecture is increasingly losing ground to the industrialized materials. Despite the fact that the constructions with sheets of asphalted cardboard offer worse conditions of habitability, they are preferred because its handling and placement is simpler than the former, as well as they represent a superior status than the one of the houses of adobe and thatch.

Through the research of traditional architecture, we can claim the concept of adobe and thatch housing and learn from its architectural design and living patterns of seasonal migration to reintroduce it in the current architecture and reduce global energy consumption in the domestic sector.

Vernacular Architecture and Lessons of Sustainability: A case study of the old city of Salt, Jordan

Rana Matarneh and Ihsan Fethi

Amman Ahliya University, Amman, Jordan

Abstract: Much of the vernacular architecture in Jordan and elsewhere in the Middle East has suffered considerable loss and replacement by modern development. Only a few examples of authentic vernacular villages and old towns remain today. Traditional architectural design principles such as passive cooling and ingenious sustainable solutions were discarded in favor of wasteful modern technologies. The aim of this study is to explore the sustainable characteristics of vernacular architecture in Jordan through examining its physical relationship with climate and site and its capability to provide appropriate functional and social solutions. It focuses on the sustainable environmental design aspects of vernacular architecture in the Old Town of Salt, in Jordan. Thus, a detailed survey and analysis of some selected traditional houses was conducted with respect to typology, morphology, functions, and environmental features, building materials, construction methods and cultural features. It included a comparative analysis of different typologies in respect to orientation, insulation, shading, natural ventilation, and thermal comfort within the buildings. It is hoped that some valuable lessons could be identified from such a study which would help support not only conserving such vernacular buildings but also help formulate new building design codes for modern built environment.

Keywords: Vernacular architecture, sustainability, Old Town of Salt

Introduction

Cities are large complex human settlements that are persistently subject to technological, economic, cultural transformations throughout history but not without cost to the environment. The construction industry and its activity are held partly responsible for the substantial amount of global climate change and waste emission. Buildings account for 40 % of global energy consumption, 40 % of waste products, 12 % of potable water and 38 % of all global gases emissions. Consequently, energy crisis, climate change, and environmental pollution have positioned sustainability high on the global agenda. However, the industry has played an imperative role in promoting socio-economic growth and enhancing the quality of life. Sustainable development is now nearly globally regarded as part of the environmental movement forcing the construction industry to implement the principles of sustainability and support Agenda 21 - a global agenda for the transition to sustainability in the 21st Century. The urge of satisfying occupant's best wishes of controlling indoor environment resulted continuously in designing and implementing various mechanical climatic control systems to the extent of which buildings became separated from the external environment. As occupants progressively voice their demands for better life quality via local Agenda 21 initiatives, many architects, engineers and building researchers have been encouraged worldwide to study vernacular and traditional buildings to learn their effective optimization of energy consumption and whether such lessons could also be applied in contemporary construction (Wheeler et al, 2009). Vernacular architecture, although still regarded by some as being primitive or obsolete, has always been among the foremost and prominent references in sustainability studies and field research. Regardless of how it was designed or built there are valuable lessons that should not be ignored but treasured as valuable and proven experiences in smart passive environmental solutions. This is why vernacular architecture with its broad green design approach and strong connection to collective memory and regional identity still inspires many architects all over the world. There are many outstanding and highly successful examples of contemporary architecture that is essentially based on lessons derived from vernacular buildings. This study will show how vernacular houses of Salt Town can provide real and valuable applications to today's building industry. This research attempts to answer the following key questions:

- What are the sustainable characteristics of vernacular architecture in the Old Town of Salt, Jordan?
- What are the sustainable environmental design principles of vernacular architecture in the Old Town of Salt, in Jordan?

Sustainable Development and Green Architecture

Global warming and the need to significantly reduce the present high-level of emissions of greenhouse gasses require the utilization of new strategies for indoor climatic control. The prevailing building technology and modern materials, in many parts of the world, are still much biased on high energy consumption to provide thermal comfort indoors. On the other hand, vernacular architecture, at any place, has evolved through a long time of trial-and-error experimentation to achieve more efficient and indigenous solutions. Sustainable development has been defined in many ways. Johnson and Oliver defined sustainability as the utilization of technology in a moral and social responsible manner so that created buildings and cities respect culture, environment and culture of people. Another interesting definition for sustainable development that has been widely used today is the one developed by the World Commission on Environment and Development, (1987) contends that "sustainable development ... meets the needs of the present without compromising the ability of future generations to meet their own needs". Sustainable development can be achieved by optimizing the corporate collaboration in terms of moving forward towards producing ecological green products and implementing the most effective and efficient practices that maximize the use of local resources. Alternatively, "Green Architecture" is considered as the cornerstone of sustainable development that utilizes renewable energy, local resources and site location of a building with consideration of its impact on the environment. As such, green buildings provide a set of added benefits in terms of the efficient use of resources and significant saving in water and energy consumption which will contribute to a responsible environmental sustainability (Looman, 2007). Today, Jordan, as a developing country, faces serious challenges in terms of the limited and costly use of imported energy and scarcity of natural resources. Accordingly, developing sustainability practices through understanding the sustainable environmental design principles of vernacular architecture, could show far-reaching results in tackling these challenges.

Research Methodology

The research methodology examines Jordanian vernacular architecture by using an empirical approach that combines qualitative as well as quantitative analyses. Thus, it focuses on the importance of using passive design strategies and elements for sustainable development such as the importance of using local materials and local construction techniques and methods. Salt Old Town with its unique vernacular architecture was chosen as a case-study to test the degree of the sustainability of its old traditional houses. Case studies allow exploration of theories and provide opportunities understanding and in examining them at the ground.

Description of the study area

Salt was an agricultural town and administrative center in west-central Jordan in the late 19th century (As-Salt Greater Muncipality, 2016). It is on the old main highway leading from Amman to Jerusalem (Figure 1) Situated in the Balqa highland, and rises some 820 meters above sea level. It is built on a mountainous area, close to the Jordan Valley (Figure 2 & 3). Old Salt developed around the spring in the Akrad valley and on mountains tightly clustered in groups of houses and buildings built in local yellow limestone (Figure 4). Salt is one of the most consolidated and oldest urban settlements in Jordan that still maintains a significant part of its original character until this day (al- Hassan, 1995).

Figure 1. Salt map

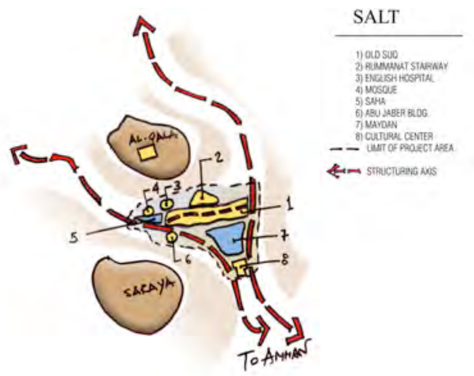

Figure 2. Urban structure of Salt

The oldest part of the existing fabric of the Old Town goes back to around 1850 when the Town began to attract migrants from the surrounding region and witnessed a prosperous period. Vernacular architecture of Salt Old Town is described as a blend of art and tradition. Houses are clustered in a unique spread across the three mountains ornamented with ochre-colored masonry that characterizes this particular town (Dawood, 1994, Khirfan, 2016).

	
Figure 3. Urban form of Old City As-Salt	Figure 4. Panoramic view of salt

Sustainable characteristics of vernacular architecture in the Old Town of Salt

Sustainable Site Planning

A major feature in the construction of the overall form of Salt is the sloped mountainous structure of its site. Thus, its fabric was shaped according to the topographic characteristics and spatial organization between different activities and zones within the old city were formulated in consideration of the climatic issues such as: the sun, prevailing wind and view of the site. Thus, geographical and climatic features of Salt had played a crucial role in determining the old town pattern, morphology and structure. The structure of the town was planned with narrow and windy streets that harmonized with the mountainous feature of the town as well as with the climate so as to offer residents shade protection from direct sunlight (Figure 5). While main streets went along the steep inclination in winding zigzag fashion, public steps were steeply inclined and took straight lines to reach the upper levels.

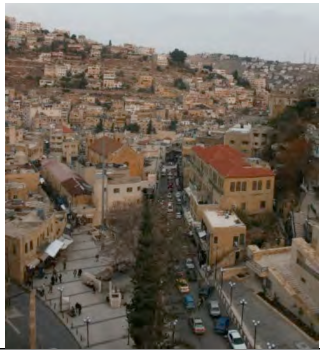

Figure 5. Winding zigzag fashioned streets in the historic core of salt

Having to settle on such a mountainous area meant a strong physical impact on its urban pattern which resulted in the utilization of terraced housing design as the basic building model. Settlements were influenced by topography so that buildings located on the slopes are connected with each other by steps which are accessible from stepped passages so that none hampered or closed off the view of another. Steps usually functioned as a public socio-cultural space where people met and communicated, and at the same time, they created the richness and variety in human circulation patterns in Old Salt (Figure 6). It may be concluded that local builders were aware of the natural potential of the site and, consequently, used it to achieve maximum benefits.

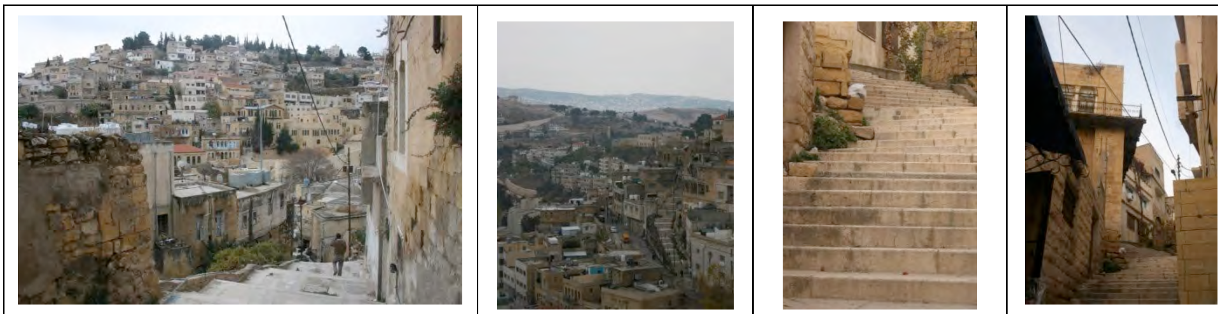

Figure 6. Urban stairs

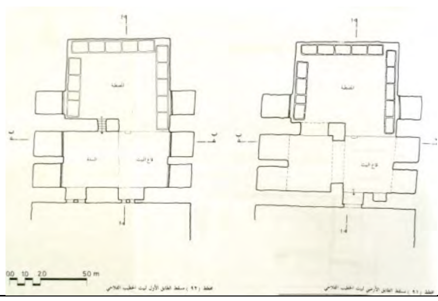
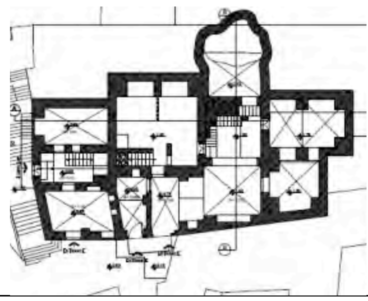
Building Typologies

Building Layout

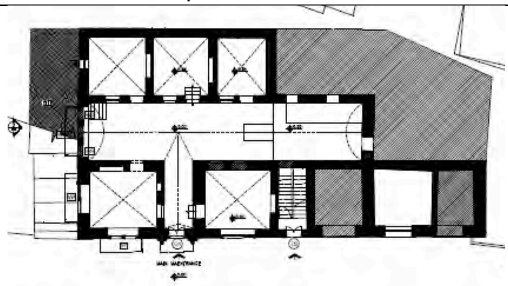
The building layout is a determining factor that enhances energy efficiency and imposes a degree of control over the climate conditions. Usually, the typical shape design varies as per to the cultural, historical, and urban planning traditions. Salt vernacular houses may be categorized into four main plan types: Basic peasant, courtyard, 3-bays houses, and detached villas (Figure 7).



a. peasant houses



b. Courtyard houses



c. typical 3-bay system houses

d. detached villa type

Figure 7. Salt's vernacular houses' typologies

A detailed typological analysis of Salt's houses is beyond the scope of this paper but some concise description is necessary. The evolution of vernacular houses in Salt Town is seen as a development model from the basic so-called spontaneous one floor "Peasant" house to the more elaborate other three, multi-story, urban types ending with the detached villa-type (Figure 7-a, 8-d). Houses seemingly formed irregularly due to the extension of rooms usable spaces inside the buildings or the construction of new neighboring buildings in the surrounding landscape. Generally, their contour followed irregular outlines of property boundaries to maximize the farmstead. However, the internal courtyard is found usually in more regular and large geometric land plots.

In the urban context, or where buildings are extensively connected, the courtyard may not appear as single but rather as several shapes where each was used to meet diverse functional and spatial needs. Significantly, the courtyard served not only as circulation zone, but also as one of the most important environmental parts of the passive cooling systems as outdoor and as living and working space. It is believed that the size of the courtyard is important to achieve an optimal level of both cooling and heating efficiency that is vital in hot and cold climates. The standard courtyards that are used in Salt's vernacular houses are relatively large, and with proportion that enhanced energy savings by offering adequate shading and maximize the gains during winter. Furthermore, they operated as a microclimate that harmonized the interior compared to the external environment. The northern cold courtyard and the southern warm courtyard were designed deliberately in order to provide adequate thermal comfort in the buildings by means of evaporative cooling and cross ventilation (Figure 7-b). The cold courtyard considered to be shaded in most of the daytime so that the flow of cool air into the building during the hot weather.

The central-hall, three-bay plan type (Figure 7-c), became the favored model for the prosperous middle class because it reflected the prevailing fashion in Greater Syria which then included Palestine and Lebanon. This plan type was an enclosed model that depended on a central hall for circulation on both two floors. The tripartite division of internal spaces was reflected on external facades and even on window shapes (Figure 8-a).

Orientation

Building orientation in Salt vernacular buildings was a successful method to enhance the effectiveness of the passive climate control. It has been noticed that, wherever possible, buildings were oriented towards the south and extended along the east-west direction with the intention of utilizing the passive heating which is supplied by the solar radiation. The overall area of openings on the north façade was the largest portion of the total area on exterior walls in order to reduce heating energy demand in the building. Orientation has been considered by traditional builders in most vernacular houses in Salt Old Town.

Openings

Salt's vernacular architecture, which developed over many decades, maintained an optimal interaction with climatic conditions especially the hot- arid summer. This essential fact, together with topography, governed the shape design of its buildings. Thus, the location of openings, size, height, and shape (i.e., straight lintels or tall arched with clear story windows) were used to provide natural daylight and good ventilation. In all Salt's vernacular houses, it is evident that careful consideration was given to the placement of openings on external walls as well internal courtyards in order to regulate wind and entice breeze (Figure 8-a).

		
		
a. Multiple tall-arched with	b. Cross-vaulted courtyard	c. Domed- roofs with thermal

Figure 8. Salt's vernacular houses' openings & roofs

Building materials, Resources and construction methods

The efficient use of materials is another track in achieving energy-efficient designs that interactively control climatic conditions. Traditional builders used local natural materials such as stone, brick, and wood that were tentatively renewable and which were generally rich in embedded energy and had the least degree of toxicity. They utilized materials of high thermal capacity for walls and roofs to regulate the temperature internally. These materials were known for their efficiency, in which they required less processing and were less damaging to the environment.

Thermal mass is a terminology used to identify materials that have the ability to absorb and store considerable quantities of heat to be embedded in masonry walls, roofs and floors. Salt Old Towns' walls were built typically using similar construction method. Buildings in Salt were constructed of abundant natural materials available in its geographical topography until the mid of the 20th century. Additionally, mud, straw, adobe and stone walls were being used as thermal masses because they were characterized by their capacity to limit the penetration of heat during the daytime and exchanging this heat externally during the night. Moreover, these materials were capable of creating 'flywheel' effect. Thus local materials were applicable choices for a good solution to control solar radiation to achieve sustainable energy performance. Vernacular houses of Salt employed domes and vaults widely to cover their rooftops. Vaulting, both barrel and cross-vault, was an ancient structural system that was used as an alternative to timber which was a rare material in the area. Barrel vaulting worked well for long narrow spaces while cross vaults and domes suited square spaces well (See Figure 8-c). Vaults were used as an essential element since it used locally available natural stones, and offered the possibility for natural sky-lighting, passive cooling**,** and ventilation. The warm air-flow under the vaulted roof through the openings placed on the far sides of the vault. Apparently, the key factor in determining the design of the vaults was the direction of the prevailing wind which was north-westerly in direction.

Conclusion

Salt Old Town is an extraordinary model representing an optimum harmonization of ecological, economic and physical factors which enhanced the integration of **s**ite, building development and cultural landscape. Hence, a proper site management enabled builders to capture the land's potential views, energy access including solar system, cooling from prevailing wind by lessening disturbance to the site and surrounding areas. Obviously, they have ideally applied, or knew how to apply, environmental and cultural resources that boosted energy efficiency. However, climatic conditions of Salt played a crucial role in transforming the vernacular architecture technologically. Moreover, the overall vernacular construction process of the old Town of Salt shows a clear manifestation on genuine architectural solutions that reflected the human desire for a truly functional, economic and comfortable environment.

This study proved that sustainability in old Salt houses was a necessity and a 'way of life'; not just a concept or an incidental social belief. Learning from traditional builders, we should go beyond the geometrical and physical calculations, formalistic notions and symbols, to a more focused attitude toward the harmonious relationship between man and nature. Perhaps, what matters really in vernacular architecture is not the traditional building themselves or their styles but, rather, the consistent respect for the natural environment and the basic principles of sustainability. Salt's vernacular architecture has a proven track record in terms of using sustainable materials, designs and construction methods that have been incorporated to cope with the local environment.

Design to Thrive

Investigating the effect of the Takhtabush on the courtyard thermal performance

Mady Mohamed

Department of Architecture, Effat University, Jeddah, KSA (On Leave, Zagazig University)
momohamed@effatuniversity.edu.sa

Abstract: The Takhtabush "A covered outdoor sitting area at ground level" was introduced in the Mamluk period in the 12th century to the traditional courtyard in Egypt (El-Shorbagy 2010). It is located between the shaded courtyard and the backyard, opening completely onto the courtyard and through a Mashrabia onto the backyard which ensures a steady flow of air by convection (Fathy 1986). Several studies investigated the thermal performance of the courtyard and few of them highlighted on the importance of the Takhtabush. No one investigated how far the Takhtabush can affect the thermal performance of the courtyard. The author of this paper doubts the efficiency of the courtyard without the Takhtabush in hot arid zone where the air velocity during the summer is very low most of the time. The current research conducts a comparative study between two scenarios of the courtyard (with and without the Takhtabush) through technical investigation. The investigation is done using monitoring techniques with observation and field measurements. Data is analysed using statistical analysis software. The results showed quantitatively and qualitatively the importance of employing the Takhtabush to enhance the thermal performance of the courtyard.

Keywords: Courtyard, Thermal Performance, Takhtabush

Introduction

Houses represent the background or framework for human existence (El-Shorbagy 2010). Through history, people have tried to adapt their buildings with the harsh climate in the hot-dry zone through reducing heat impacts (Mohamed, Osman et al. 2010). They used to open their houses onto a private internal open space that visually and acoustically separated from the outside called Sahn "courtyard" (Afify 2002). The courtyard helps in maintaining cooled indoor temperatures by employing the phenomenon of the stack effect (Wazeri 2002). Stack effect occurs when the air inside a vertical stack is warmer than the outside air (provided that there are both inlet and outlet openings). The warmer air will rise and will be replaced at the bottom of the stack by cooler outside air (Szokolay 2014). With some modifications to the courtyard such as using water and vegetation in its landscape, the benefits of the thermal performance could be maximized.

With the development of architecture and technology people have neglected the traditional architecture in terms of techniques. One of these marvellous techniques is the Takhtabush (Figure 1, Figure 2 and). It is an important component of the Arab house which ensures a steady flow of air by convection. Since the backyard is larger and thus less shaded than the courtyard, air heats up more readily there than in the courtyard. The heated air rises up and draws cool air from the shaded courtyard through the Takhtabush, creating a steady cool breeze (Fathy 1986). Figure 3 illustrates the created air flow through the Takhtabush.

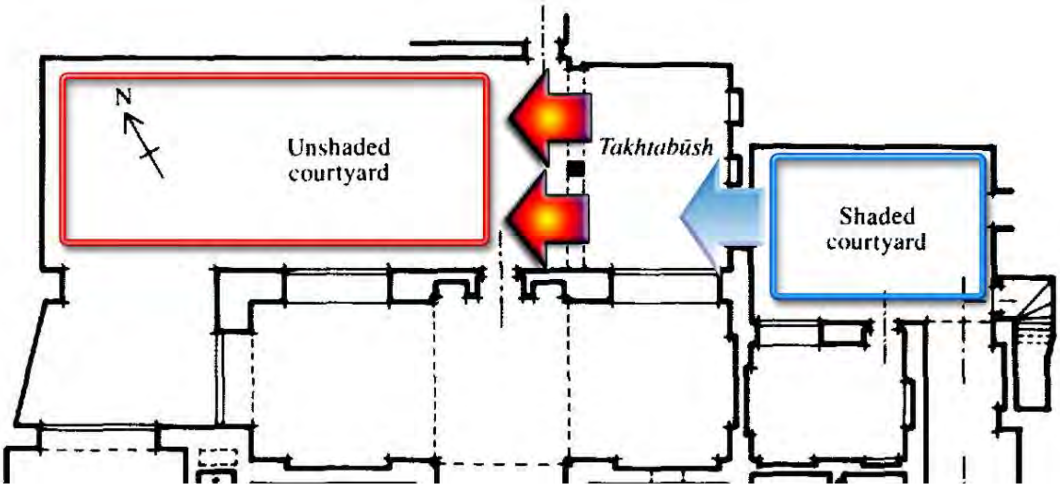

Figure 1: Plan of the part of the ground floor of the Qã 'a of Muhib Ad-Din Ash-Shãf 'i AlMuwaqqi at Darb Al-Usta, Cairo, showing two courtyards with a Takhtabush between them, by the author after (Fathy 1986)

Figure 2:The Takhtabush of al-Souhimi house, Cairo, (captured by the author)

The original houses could be considered an exception in nowadays urban environment with the high density urban areas. However, the concept of the Takhtabush still can be applied on new small houses through different techniques. Since, the required large area for the backyard could be replaced by the solar chimney. Mohamed (2017) confirmed in a previous work the effectiveness of utilizing the solar chimney to replace the large backyard in the Takhtabush system.

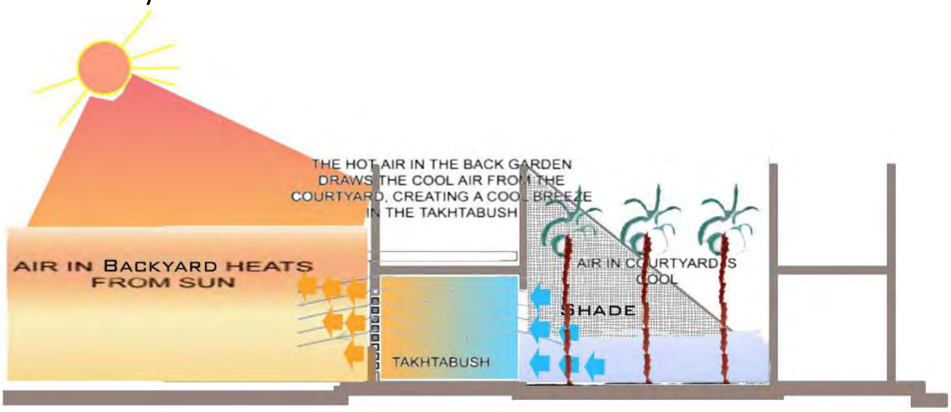

Figure 3: The air flow from the shaded courtyard to the backyard through the Takhtabush, by the author

Research Aim and Objectives

The research aims at quantifying the effectiveness of the Takhtabush on the thermal performance of the courtyard, through the following objectives:

1. Analyse the importance of the Takhtabush through the literature review;
2. Test the performance of two courtyards representing the proposed scenarios (with and without the Takhtabush);
3. Compare and analyse the results of the two scenarios.

Research Methodology

The current research conducts a comparison study between two scenarios of the courtyard (with and without the Takhtabush) through technical investigation. Two courtyards of two different precedents representing the two scenarios, located in the same climatic region (Cairo, Egypt) are monitored at the same time to compare their thermal performance. The two case studies are: Buit Al-Souhimi (The one with a Takhtabush) and Gamal El-Din Al-Zahabi House (The one without a Takhtabush) (Figure 4). The two courtyards are almost similar also in dimensions, height, and vegetation. This is to assure that the variations in the measurements are affected mainly by the existence of the Takhtabush.

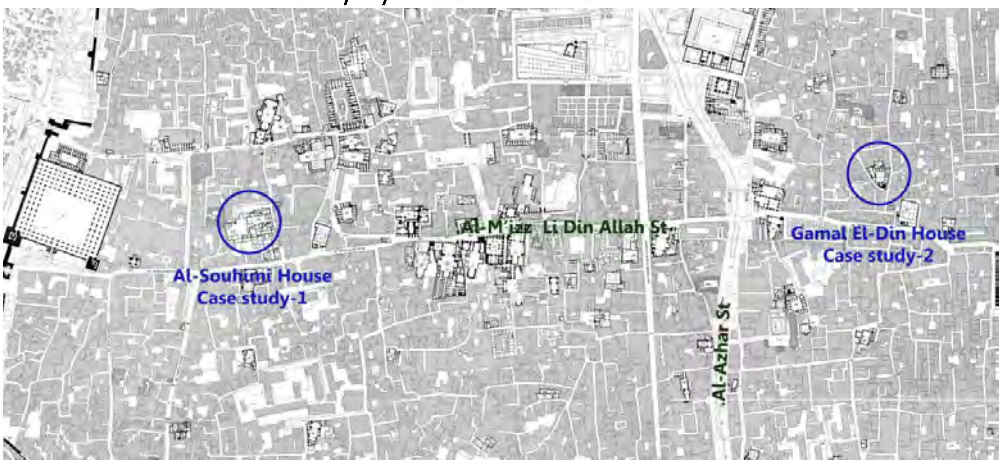

Figure 4: A map of Old Cairo shows the location of the two case studies, after (Warner 2005)

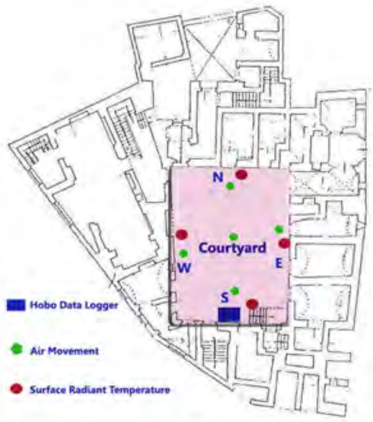

Figure 5: The ground Floor of Gamal El-Din House showing the location of the measurements, by the author

Objective assessment was done using observation and field monitoring techniques Figure 5 and Figure 6 show a ground floor plan for each house with the location of the different measurements inside the courtyards. The measurements included;

1) Monitoring the air temperature of the two courtyards – as the most representative indicator for thermal performance – and the Relative Humidity (RH) using Hobo Data Loggers

H12[1] (**Error! Reference source not found.**). The Data loggers were fixed at the middle of the two courtyards on the same wall orientation (The southern wall[2]) for the whole summer season (from 21-June to 21-September). The time interval was 15 minutes;

2) Data is analysed using statistical analysis software SPSS to quantify the difference in thermal performance between the two courtyards through Mann-Whitney U test[3](Hague and Harris 1993).

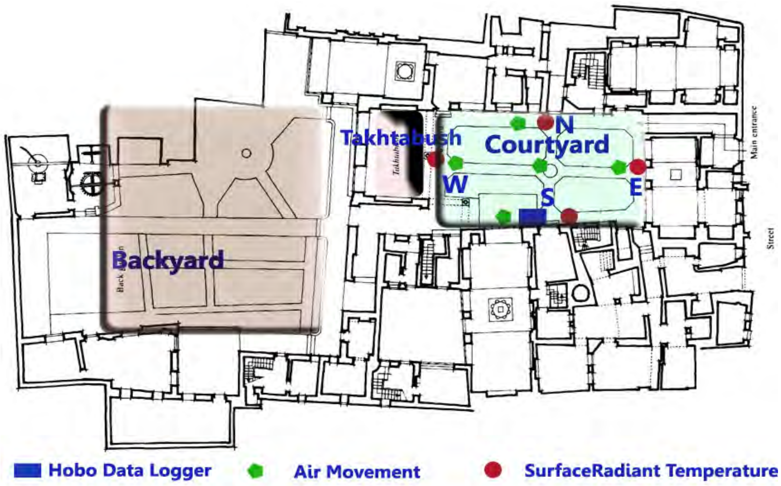

Figure 6: The ground Floor of Al-Souhimi house showing the location of the measurements, by the author after

3) Measuring the Plain Radiant Temperature of the surfaces using MicroRay Pro Infrared Thermometer[4] (Figure 8), and the air movement (wind speed) using Hand Held Anemometer-Sky Master[5] (Figure 9) over different points inside each courtyard for the one daytime on interval of 30 minutes. The 21st of June was selected to represent the worst case scenario, since this day is one of the hottest days over the whole year in Cairo. The noon time from 12:30 to 16:0 O clock, was chosen to represent the hottest time during the day. This will help later to measure the Predicted Percentage of Dissatisfied index (PPD) which predicts the percentage of occupants that will be dissatisfied with the thermal conditions (ASHRAE 2013). It is a function of the Predicated Mean Vote (PMV) using the Psycho Tool. The latter is an electronic version of the psychrometric chart[6] on which human comfort, air-conditioning strate.

Figure 7: Hobo Data Logger H12

Figure 8: MicroRay Pro Infrared Thermometer

Figure 9: Hand Held Anemometer- Sky Master

[1] Hobo Data Logger H12, a device to log the air temperature and relative humidity at certain intervals for a period of time, shown in **Error! Reference source not found.**

[2] Since the courtyard is opened to the sky and receive sun radiation which affect the data logger readings, the only side that is not receiving any solar radiation during the whole day is the south wall that facing the north direction.

[3] Mann-Whitney U test is like t-test but does not require the assumption of normal distribution for the values of the two samples

[4] MicroRay Pro Infrared Thermometer, a device to measure the air velocity at a time

5 Hand Held Anemometer- Sky Master, a device to measure the radiant temperature of a surface by Laser techniques

[6] A psychrometric chart is a graph of the thermodynamic parameters of moist air at a constant pressure, often equated to an elevation relative to sea level

The PMV/PPD index predicts the thermal comfort of people in a given environment. It employs both the environmental and human factors that affect the thermal comfort, and has become the most widely used index in recent years (Mohamed 2009). It has been adopted in the British, European and International standard (HSE 2006). According to ASHRAE (American Society of Heating, Refrigerating, and Air-Conditioning Engineers) these indices combine the influence of air temperature, mean radiant temperature, air movement and humidity with clothing and activity levels into one value on the thermal sensation scale Figure 10 (ASHRAE 2005). The PMV index may be defined as the mean value of the votes of a large group of persons, exposed to the same environment with identical clothing and activity (CIBSE 1999)

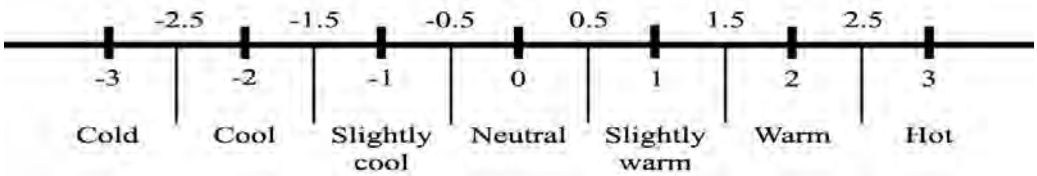

Figure 10: The thermal sensation seven-point scale, after ASHRAE (ASHRAE 2005)

Predicted Percentage of Dissatisfied (PPD) predicts the percentage of occupants that will be dissatisfied with the thermal conditions. In the PPD-index, people who vote -3, -2, +2, +3 on the PMV scale, are regarded as thermally dissatisfied (INNOVA 2004)

Results and discussion

The air temperature degrees of the two case studies were monitored for the whole summer season on 15 minutes intervals. The temperature degrees ranged from 24°C to 46°C. The average temperature for case study-1 (Al-Souhimi house) was 28.46°C while it was 29.56°C for case study-2 (Gamal El-Din house). On comparing the air temperature degrees of the two courtyards by applying Mann-Whitney U test on the air temperature data for the summer season (21st June to 21st September), the results revealed a significant difference ($P<0.05$)[7] between the two case studies, despite the two sets of data trends being consistent. Table 1 presents the statistical analysis output from the SPSS software.

Table 1: Statistics comparison between the hourly air temperature degrees of the two courtyards

Comparison Item	Al-Souhimi	Gamal El-Din
Mean temp.	29.09	30.57
T- Test	P=0.03	
The difference between the two sets of air temperature at the two courtyards (S=Significant)	S	

Figure 11 shows the air temperature for the two cases on a selected day (21st June). The graph clearly presents the significant difference between the thermal performances of the two courtyards. The temperature degrees for case study-1 (Al-Souhimi house) ranged from 25°C to 35°C while it ranged from 27.5°C to 41°C for the other case study. It is obvious that the highest difference between the two case studies is occurred during the noon time. To understand this behaviour, it was important to measure the radiant temperature on the surfaces of the courtyards and the air velocity inside the courtyards.

[7] In the majority of analyses, an alpha of 0.05 is used as the cut-off for significance. If the p-value is less than 0.05, this confirms the hypothesis that there is a significant difference between the means. If the p-value is larger than 0.05, this proves the Null-Hypothesis of no significant difference exists Hague, P. and P. Harris (1993). Sampling and Statistics, Kogan Page.

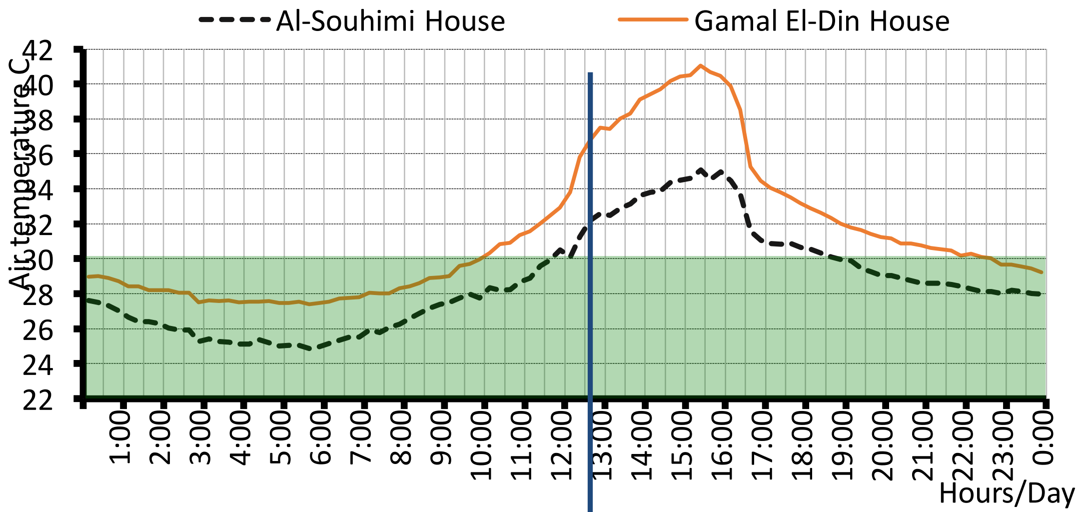

Figure 11: Air temperature of the two courtyards on 21st June for the whole day

Table 2: Surface RT and RH of the two courtyards at 12:30 pm

Surface RT	**Al-Souhimi House**	**Average RT**		**Gamal El-din House**	**Average RT**
North	31.8	29.7		32.6	31.05
East	28.6			30.2	
South	29.7			31	
West	28.8			30.4	
Relative Humidity RH	41%			37%	

Table 2 shows the SRT (Surface Radiant Temperature) and the RH (Relative Humidity) inside the two courtyards of the case studies at 12:30 pm. The average Surface Radiant Temperature SRT at Al-Souhimi courtyard is 29.7 °C which is lower than the average SRT at Gamal El-Din courtyard by 1.35. The relative Humidity RH at Al-Souhimi courtyard was 41% while it was 37% at Gamal El-Din courtyard.

Table 3: Wind velocity at the two courtyards from 12:30 to 16:00 afternoon

Wind speed	**Al-Souhimi**									**Gamal El-din**							
North	1	0.9	0.7	1.1	1.6	1.4	0.8	0.3		0.6	0	0.3	0.5	0.4	0.5	0.5	0.3
East	0	0.5	0.6	0.5	1	1.1	0.9	0.2		0.3	0.2	0.3	0.6	0.3	0.5	0.4	0.3
South	0.5	0.7	0.8	0.6	0.6	0.5	0.5	0.3		0	0	0	0	0.3	0.2	0.2	0.4
West	1	1.2	1.1	1.4	1.6	2	1.2	0.9		0	0.6	0.1	0	0.3	0	0	0
Centre	0.9	0.9	0.8	0.9	1	1.1	1.0	0.9		0.4	0.1	0.5	0.6	0.5	0.5	0.6	0.2

Table 3 presents the wind velocity at the two courtyards at intervals of 30 minutes from 12:30 pm to 16:00. The measurements were taken at different five points as shown before in Figure 4 and Figure 6 which are at the four sides of the courtyards in addition to the middle points. It is evident that the air movement inside Al-Souhimi courtyard was higher than Gamal El-Din courtyard most of the time, if not all the time. This confirms the efficiency of the Takhtabush in accelerating the air velocity inside the courtyard. In addition, it explains the differences in the surface radiant temperature of the two courtyards, since the air movement decreases the surface radiant temperature from the construction.

Figure 11, reveals a significant decrease in the air temperature during the noon time at case study-1 compared to case study-2. Based on the results of the SRT and the air velocity, it is evident that the phenomenon of the stack effect that manages to create a steady cool breeze between the shaded courtyard and the backyard through the Takhtabush works successfully at Al-Souhimi house.

In order to quantify the effectiveness of these differences of measurements on human thermal comfort, the PMV and the PPD were calculated for the two case studies on 21st June at 12:30 pm. Figure 12 and Figure 13 present the PMV and the PPD for occupants inside the two courtyards at 12:30 pm on 21st of June. The clothing level was assumed 0.6[8] clo which refers to light clothes (trousers and shirt), while the occupant activity was assumed 1.5 met (metabolic rate[9]), which refers to standing occupants with light activity with metabolic rates ranging from 1.2 met to 1.5 met.

Although both values of the two case studies show discomfort levels for the occupants because of the chosen time from the year and the day, it is clear that the thermal performance of the Al-Souhimi courtyard is better than the other case study. While PMV was 2.7 on ASHRAE Scale for Gamal El-Din courtyard, which represented HOT thermal condition for occupants, it was 2 for Al-Souhimi courtyard which represented WARM thermal condition for its occupants. As for the PPD; it was 97% for Gamal El-Din courtyard which means that almost all occupants would be dissatisfied at the that time, while it was 75% for Al-Souhimi courtyard which means that not all occupants are dissatisfied, where 25% of the occupants are satisfied with the thermal condition.

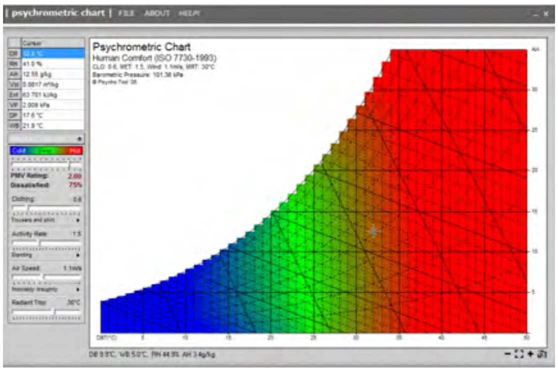

Figure 12: PMV and PPD for occupants at Al-Souhimi courtyard at 12:30 on 21st of June using the Psychrometric Chart

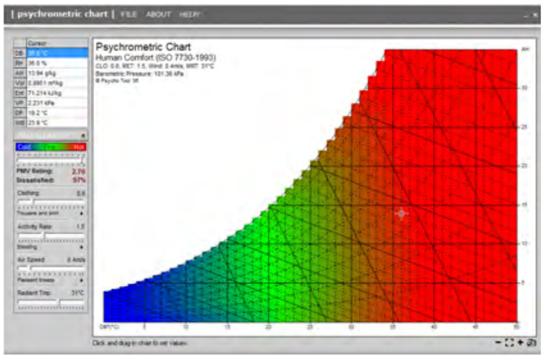

Figure 13: PMV and PPD for occupants at Gamal El-Din courtyard at 12:30 on 21st of June using the Psychrometric Chart

Conclusion

An objective assessment for two scenarios of courtyards in old Cairo was carried out in this research. The two courtyards were almost architecturally similar to each other except the attached Takhtabush which exists in the first case study (Al-Souhimi house) and does not exist in the second case study (Gamal El-Din house). Air temperature, RH, Air velocity, and Surface RT were monitored and measured during the same times and intervals. PMV and PPD for occupants were evaluated based on the collected data. On analysing the measurements, it was obvious that the thermal performance of the first case study (courtyard attached to Takhtabush) was much better than the second case study (courtyard without Takhtabush). This has been shown clearly through the following results:

- P-Value was <0.05, revealed that there is a significant difference between the air temperature degrees inside the two courtyards during the summer season (21st of June

[8] 1 clo = 0.155 m^2 °C/W, where m = area, C = degrees Celsius, and W = watts

[9] The metabolic rate characterizes the energy generated inside the body due to metabolic activity. The standard unit for metabolic rate is the **met**. 1 met = 58.2 W/m^2 (18.4 BTU /h ft^2)

to 21st of September);

- Air temperature degrees inside case study-1 are much lower than case study-2 and particularly during the noon time because of the steady air flow caused by the Takhtabush;
- PMV and PPD were much better in case study-1 than case study-2 by about 25% which confirms the effectiveness of employing the concept of the Takhtabush in today's designs in the hot zones of the world.

Abstract: India is known for its embedded rich culture and heritage. In India, especially in rural areas some of the communities have a unique settlement pattern and architecture due to climate, topography and availability of materials. The culture and architecture are closely knitted with each other. The architecture of *Rajwar* community of Central India has a unique style. It is the finest example of bas–relief architectural ornamentation in India. The paper aims to study the aesthetic aspect of the vernacular architecture of *Rajwar* community of Central India. The objective is to understand the social and cultural aspect of this community and its reflection in architecture. The methodology adopted is to document and analyse the aesthetic aspect of the vernacular architecture of this particular region. Documentation is done in the form of sketches, drawings and photographs. The experts and artisans are also interviewed. The aesthetic analysis is done on different aspects of visual art forms namely sculpture, painting, bas- relief, design patterns and colours which are inbuilt in the construction. Paper concludes that the architecture of *Rajwar* community is a true reflection of their culture. The ornamentation is not mere a decoration but a ritual representing their beliefs and way of life.

Keywords: Vernacular, Architecture, *Rajwar,* Ornamentation, Aesthetics

Introduction

India has a rich tradition and culture which reflects in its vernacular architecture. In the vernacular architecture of Central India, the architecture of *Rajwar* community is unique in its style. It is the finest example of bas-relief architectural ornamentation in India. Such architecture survives only because of its beauty and aesthetics. Its tradition is still transferring from one generation to another. Due to its architectural character, it can be easily identified that this village belongs to *Rajwar* community. In its basic form and space planning it is not different from other vernacular architecture of the region but in its ornamentation, it is entirely different.

"*Rajwar* houses are amongst the finest example of rural aesthetic sensibility for, though decorative, they have an austere beauty and simplicity about them. Beautiful lattice work in clay adorned with simple figures all painted in white and subdued colour give the house and auspicious aura" *(Shah*, 1996:95).

The population of *Rajwar* community is around 600,000 and is widely spread in Chhattisgarh, Madhya Pradesh, Bihar, Jharkhand, Orissa and West Bengal. In India, it is densely populated in *Sarguja* district of Chhattisgarh. In Chhattisgarh, this community is found in village namely *Ambikapur, Baikunthpur* and *Surajpur.*

Figure1. Map of India

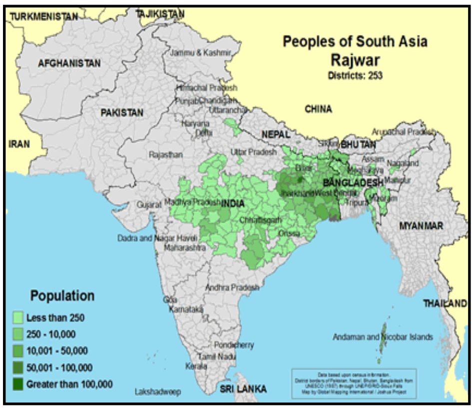

Figure2. Map Showing Population of *Rajwar*Source:https://joshuaproject.net/assets/media/profiles/maps/m1

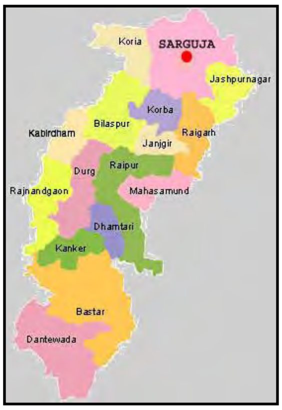

Figure3. Map of Chhattisgarh

Aims and objective

The paper aims to study the vernacular architecture of *Rajwar* community from Chhattisgarh, Central India. The objective is to understand its social and cultural aspect of this community and its reflection in the architecture. Analyse the aesthetic aspect of the vernacular architecture of this particular community of this region.

Methodology

The methodology adopted is to document and analyse aesthetic aspect of the vernacular architecture of this community. For the case study selected a *Rajwar* dwelling constructed by *Sundari Bai* and *Pandit Ram* at Indira Gandhi *Rashtriya Manav Sangrahalaya*(IGRMS) (National museum of Man) Bhopal, observed and also studied Exhibition at visual Art Gallery at Tribal Museum at Bhopal and Tribal Art Gallery at *Bharat Bhavan*, a multi- arts Complex Bhopal, India. We witnessed the construction of documented dwelling, interacted with artisans and learnt the techniques of making lattice with mud and bamboo, relief work and terracotta decorative roof tiles. The documentation is done in the form of sketches, drawings and photographs. Observed different visual art forms sculptures, paintings, bas-reliefs and analysed different design patterns which are in practice**.**

In *Sarguja* district of Chhattisgarh, the villages exhibit some of the finest bas- relief architectural ornamentation in India. In most of the rural villages, women sculpt clay bas-relief on the walls during the construction. The style of sculptures in these regions is from extremely minimal to highly complex. This unique style is known as *Sarguji.*

Figure4.&5. Construction of *Rajwar* dwelling, IGRMS, Bhopal Source IGRMS

Figure6. *Rajwar* dwelling, IGRMS, Bhopal all four side views Source *Abid Baig*

Planning

Rajwar dwellings usually are formed around a courtyard surrounded by a columned veranda, of which radiates kitchen, bedrooms and store room. Grain bins sometimes used to segregate spaces. Usually, there is only one door and no windows outside. A small typical rural dwelling is taken for case study at IGRMS. There is no courtyard in this dwelling. In front and left side there are verandas. On right and back side there are no doors and windows.

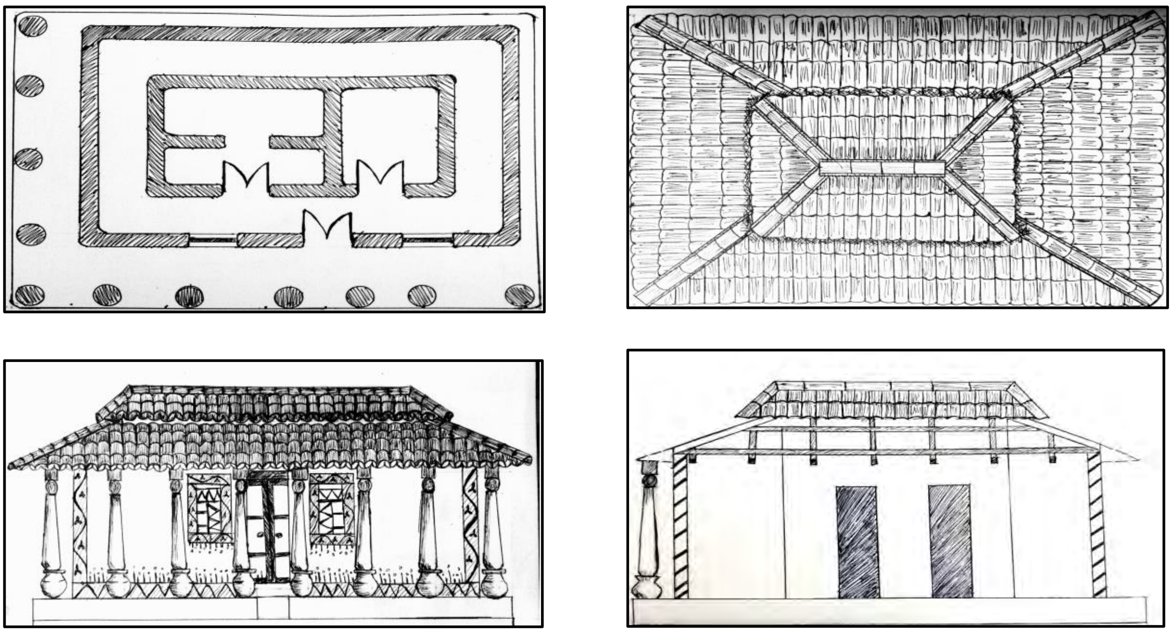

Figure7. *Rajwar* dwelling IGRMS, Bhopal Ground Plan, Roof Plan, Elevation and Section Source *Kirpa John*

Figure8. IGRMS,Column Figure9. Grain Bin Figure10. Door Figure11. Window Source *Vikas Patidar*

Construction

It is common in Indian villages all the members of the family contribute and collaboratively construct their dwelling right from procuring the material till finishing. All the dwellings in this region are constructed in a similar manner using locally available materials and techniques. Although they are constructed in the same manner still each one is different in its style. The dwellings are decorated when they are first built, again when rooms are added and on the special occasions on festivals like Diwali. Before starting their work they pray let all the elements of cosmic world, nature, animals, God and Goddess adorn their house.

Walls

The foundation is made of random rubble masonry. The wooden pillars are placed on wooden or stone pedestal of the unique shape of a pot and beams held with decorative capitals and brackets together (Figure8) Adobe wall is made with mud mortar, clay, cow dung and straw. The interior walls are decorated with bas- reliefs depicting images of their activities of day to day life (Figure18) dance forms, landscapes, fields, house, animals, God-Goddess. They are painted with different natural colours. Some of the walls are painted soft white interlaced finger pattern of lines *Leepan* (coating) (Figure27) horizontal, vertical, diagonal or curved named after the shapes they resemble.

Doorways-windows

The doorways (Figure10) and window frames (Figure11) are decorated with simple designs made up of clay that the simply sculpted design and patterns around the perimeter of the front door and painted with red, yellow ochre or black so that it stand out against the whitewashed walls. The pigments are made with different vegetables herbs spices and minerals. Bright green made of leaves, the yellow mixture of spices and minerals, red ochre from red oxide, black made from black clay and burnt leaves and blue from indigo is used.

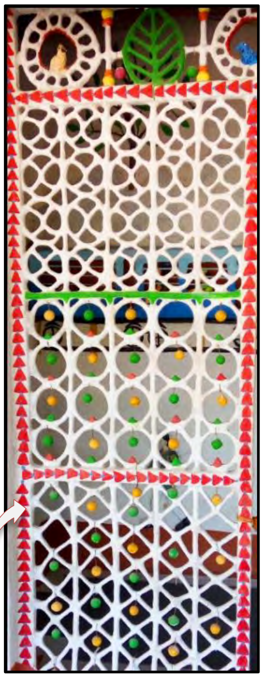

Figure12. *Sakarpara*

Figure13. *Dharibani*

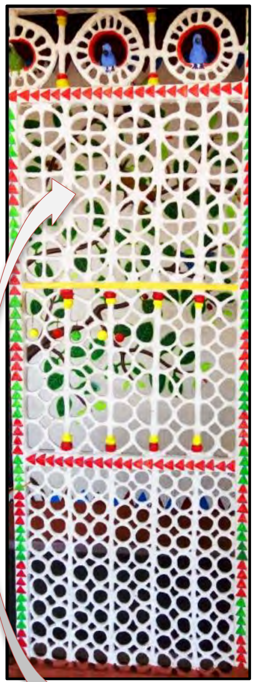

Figure 14. *Seekabani*

Figure 15. *Machlikanta*

Lattice

To soften the light and lessen its intensity screen, made of bamboo and mud is created in the veranda. This screen, the lattice is called *jali* (Figure12) which is created between the width of supporting pillars of the veranda and the height between the roof beam and the floor. It is made up with a thin bamboo strip cut and tied together to build a simple grid in the space. Then strips from another piece of bamboo curls into the round circle fasten each other with a small piece of twine and joined them all between the grids. To create the screen the clay added to the edges and bamboo circles smoothen into the rounded supports and blended the entire screen into the surface of the pillars.

The sculptures are made by rice straw tied tightly with the string and supported by bamboo sticks covered with wet clay smoothen to get the desired form after drying it is painted with bright colours the images of people (Figure18) animals (Figure19). Some sculptures toys, dolls, animals, insects and idols of God-Goddess are made of bamboo and clay enhance the beauty of the lattice. The images of Goddess *Saraswati, Laxmi, Durga* and God *Ganesha,* Hanuman (Figure24) and Krishna (Figure25) are introduced for particular festivals like *Dussehra, Diwali* etc. These sculpted lattices create a light and shadow effect in front of recessed niche and shelves. In the designs of lattice intricate geometric pattern are created with parallel, criss-cross, diagonal, zigzag and circular lines. These patterns are simple and complex too. Some designs are repetitive some are the combination of two-three forms.

The decorations are done all around the dwellings on the edges of the courtyard, on the steps, in the verandas, in the kitchen, bedroom and store room and even on the Grain bins. Auspicious symbols drawn on walls and floors during the festival, rituals connected with seasonal changes sowing of crops, harvest or special occasions of the family such us birth puberty, marriage, pregnancy and death these symbol drawn afresh each time.

Aesthetic Analyses

Rajwar art tend to free itself from the constraints of naturalism, this art derives its substances from nature, depicting birds, animals, trees does not render it in a natural manner. By observation the design patterns found in architecture of *Rajwar* are named after its resemblance to the objects of surrounding like house, basket, temple, grain bin etc. Design patterns found in this vernacular architecture style are following;

Kothi (Grain bin Pattern) (Figure9): This pattern is evolved from grain bin used for keeping grains. The grain bins are decorated with bas- relief.

Shakarpara (Diamond Shape) (Figure12): This pattern is evolved from *Shaker para*, a sweet dish made in a diamond shape. It is formed by a crisscross of diagonal lines.

DhariBani (Line Pattern) (Figure13): These design patterns are made spontaneously with the movement of fingers. The walls are painted with a unique style. In this design pattern parallel vertical and horizontal lines cut each other and from rectangular and square grids. In some patterns, diagonal lines crisscross each other.

SeekaBani (Basket Pattern) (Figure14): These design patterns are evolved from different bamboo baskets weaving patterns. It is clearly reflected in these designs.

MachliKanta (Fish Bone) (Figure15): This pattern is evolved from fish bone usually placed in the centre of the design and on the borders.

Ghar (House Pattern) (Figure16): The image of a hut is also used in paintings and bas- reliefs. The shape of the pitched roof is used as an element of design.

GhiriyaBani (Lizard Pattern): From the movement of moment of lizard *(Giriya)*, this pattern is evolved. The rhythm of the movement is visible in this from.

MakarBani (Spider web Pattern)**:** This pattern is evolved from spider's *(Makar)* web. It is similar as network of fine threads constructed by a spider starts from small to larger polygon in ascending order.

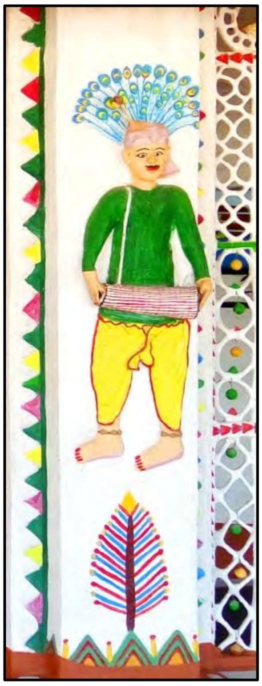

Figure20. Bas-relief,Elephant Figure21. Peacock Figure22. Snake Figure23. Dancer Source Author

Naag Bani (Snake Pattern) (Figure22): This pattern is evolved from the movement of the snake. This is mostly found in borders and on columns.

Chhohaleepan (Coating Pattern) (Figure27): These design patterns are made spontaneously with the movement of fingers. The walls are painted with a unique style.

Phool (Flower Pattern): This simplified foliate design pattern is evolved from the articulation of different followers.

Results and Findings

Aesthetics is a sense of perception. It is concerned with the nature and appreciation of art; beauty and good taste. Judgement of aesthetic value relies on sensory, emotional and intellectual level. According to German philosopher, Immanuel Kant-beauty is objective and universal. But beauty may be subjective and varies according to class, culture, background and education. The aesthetic judgements are culturally conditioned to some extent The Indian art evolved with an emphasis on inducing spiritual or philosophical states in the audience, or with representing them symbolically. In analysis *Rajwar* art fulfils the criteria of aesthetics given by the contemporary American philosopher, Denis Dutton. He has identified seven universal signatures of aesthetics

- **Expertise** - technical artistic skills are cultivated, recognized and admired
- **Non-Utilitarian Pleasure** - people enjoy art, and don't demand practical value of it
- **Style** - artistic objects satisfy rules of composition that place it in recognizable style
- **Criticism** - people make a point of judging, appreciating and interpreting works of art
- **Imitation** - works of art simulate experiences of the world
- **Special Focus** - art made a dramatic focus of experience
- **Imagination** - artists and their audiences entertain hypothetical worlds.

Figure 24. God *Hanuman*

Figure25. God *Krishna*

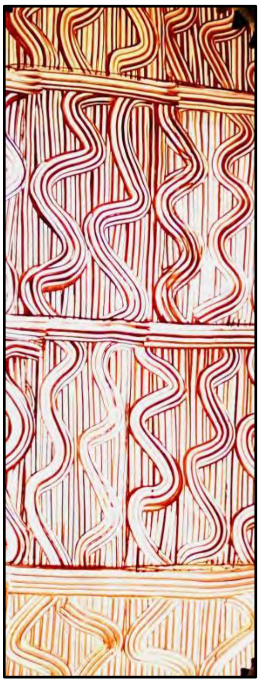

Figure26. *ChhohaLeepan*

Figure27. *ChhohaLeepan*

Conclusion

Architecture of *Rajwar* community is a true reflection of their culture. The ornamentation is not mere a decoration but a ritual representing their belief and way of life. Aesthetically it is a unique style embedded in architecture. Such integration of art and architecture is missing today. With this aesthetic sensibility contemporary architecture can also flourish.

Design to Thrive

The study of architecture of Gond Tribe of Madhya Pradesh, India

Shikha Patidar[1], Brishbhanlali Raghuwanshi[2],Eti Sharma[3],

[1] Vinyas, A Group of Artist, Architects and Engineers, Bhopal, India
[2] School of Planning and Architecture, Bhopal, India
[3] Smt.Dhariya Prabhadevi Sojatia Women's College, Indore, India

Abstract: In the 21st century, it is observed that a lot has changed in terms of Indian tradition and culture in every aspect. Sadly, this has cut the roots of the knowledge system of architecture developed by our ancestors To hide the dying blossom of traditional vernacular architecture, it is being loaded with artificial aesthetics, which forms a false image of the rich culture of India. The tribes in different parts of India are still living with their traditional knowledge system. The architecture truly reflects their culture, lifestyle, ethics and aesthetics which give special and unique character to it. The aim and objective of the study are to acknowledge, understand, observe and draw the inference from the study of the vernacular architecture of Gond tribes of *Umariya* district of Madhya Pradesh. The different types of settlement patterns of some villages are studied. The locally available material, method of construction and traditional knowledge system will be studied. The methodology adopted is to document and analyse the selected typologies. The result and findings focus on learning lessons from traditional knowledge. The paper examines some key assumptions for policy makers in planning and designing of appropriate housing and planning strategies for different tribes.

Keywords: culture, vernacular, architecture, tribe, Gond, sustainable development

Introduction

The tribes all over the world have distinct features in terms of culture, lifestyle and architecture which showcase their way of life and how they celebrate it. These characteristics have developed distinctly in all tribes over a period of time. They live in forests far away from city life and hardly mingle among each other. These distinct features can be easily seen in Gond tribes residing near *Umariya* district of Madhya Pradesh.

The Gond tribes are the largest tribal Community in India and are Dravidian's whose origin can be traced to the pre-Aryan era. The word "Gond" comes from the Dravidian expression Gond, meaning "the green mountain". For example tribal living in a village *"Chandiya"* they make their house using sun-dried bricks. They use soil in different stages of construction. Soil strengthens and beautifies the house. They have excelled the art of building simple abodes with the more natural process without harming the environment. Through their hard efforts, over thousands of years created rich and colourful styles of vernacular architecture, responding to the local environment. The reason for more percentage of tribal in the states can be attributed to the geographical locations like islands, rivers and mountain ranges.

Figure 2. Gond Paintings

Figure 3. Gond Dances

Figure 4. Map of states of India

Figure 5. The population density of Gond settlement in India

Figure 6. Map of M.P.

Aim and Objective

The aim of the study is to know about the tribal ethics and the aesthetics and understanding their ways of living develop a symbiotic relationship between them and the natural environment. Tribes nurture from the natural resources but at the same time safeguard forests and other natural resources. The main objective of the study is to observe their lifestyle and culture, analyse architecture and aesthetics. The documentation includes the study of settlement pattern and typology, considering construction technique, planning, aesthetic and response to climate and the surrounding environment.

Methodology

To learn about the Gond settlements patterns and their dwellings of some of the villages coming under district *Umariya* were studied. Villages *Ufri*, *Bhagda* and *Mahroi* were taken as case studies. The different typologies were observed and in the village *Amanhudi* the dwelling of *Ashok Singh Tekam* has been taken as a typology to study the planning and construction. The documentation is done in the form of sketches, drawings and photographs.

Figure7. Village

Figure8.Village Street

Figure9. Community space

According to the 2011 Census of India in Central India, the state of Madhya Pradesh has the highest population of tribes, which constitutes the 20.26 % of the total population of the state. Gond is the second largest tribe, with a population of 4,357,918 constituting 35.6 % of the total ST population of the State.The tribal population is 46% of the total population of *Umariya*.

The area of study is *Umariya* district, amongst 47 districts of Madhya Pradesh comprising of 660 villages surrounded by Jabalpur district from the west*, Katni* district from the north*, Shahdol* district from the east and *Mandla* district from the south. The district lies between north latitudes 23° 05' and 24° 20' and east longitudes 80° 40' and 81° 17', with a geographical area of 4503 sq km. The physiographic features include Northern Valley area, Central-Plateau area and Southern Hilly area. The southern part of this district is represented by hilly terrain, which is the northern part of *Amarkantak* hills extending in East-west direction. The highest elevation of the district is located on the southern boundary of the district near village *Singhpur* having an elevation of 980 m above mean sea level, comprising of basaltic rocks. The northern part of the district in *Manpu*r block area there is prominent valley which, almost originates from the Achaean hills and extends north wards. Major drainage is *Son*, *Johila* and *Choti Mahanadi* river.

It has abundance of mineral resources including coal and clay. Commonly found rocks are Granites, Sand -Stones, Slates, Basalts and Alluvium. Major soil type found is laterite, clay and loamy soil. It is also full of natural resources. About 53% of the area that comes about 765 acres of land is covered with forest and the rest 47 % comprises of the total sown area is 1604 acre and cropped area is 1941 acre. Common crops include paddy, maize, wheat, mustard, gramme pulses. Common trees found in forests are Teak, Haldina cordifolia, Madhuca Longifolia, Shorea Robusta and Mango. Bamboo is also found in abundance.

Climate

The Climate of this district is characterized by a hot summer and general dryness, except during southwest monsoon season. The year may be divided into four seasons. The cold season spans from December to February, followed by the hot season from March to the middle of June. The period from the middle June to September is the south- west monsoon season followed by post -monsoon or transition period in October to November.

The Gond tribes live their life within natural surroundings secluded from the outer world, with no dependence on any other community. This leads to a special and distinct character. in the evolution of settlement and the development of the architectural elements and prominently in terms of culture and traditions.

Figure10. *Devlook* (Deity)

Figure11. *Parchhi* (Verandah)

Figure12. *Kothi* (Storage)

The Gond tribes decorate their dwellings with vibrant depictions of local flora, fauna and gods such as *Marahi Devi* and *Phulvari Devi*. Traditionally made on festive occasions such as *Karwa Chauth*, *Diwali, Ashtami* and *Nag Panchmi.* The oral tradition of stories, anecdotes and folktales are very popular among them. They sing and dance on the occasion of birth and marriages. In some instances, such as with the *Dandari* dancers, dances re-tell events from Gond mythology. At other times, dances are performed simply for fun. *Dhulias* are a professional musician caste and *Pardhans* preserve legends, myths, and history, passing these traditions on from generation to generation. They have rituals and beliefs associated with trees, most villages have scared spaces under the trees. Trees with medicinal values are Ficusreligiosa, Ficusbenghalensis, Vachellianilotica.

Traditionally Gond tribes are agriculture labours, sand collectors of forest produce. They depend economically on crop produce from agriculture and little craft items and daily use items like the broom, baskets, mattresses, jewellery etc. They use bamboo, grass and mud and other easily available material to make these crafts. These distinct features of the Gond tribes not only depend on the cultural aspect but also on topography, climate and availability of materials.

Types of settlements

Settlement pattern according to contours

The growth of village is organic and the road determines the basic spatial form in which the village is evolved. In the village, the dwelling units are placed with respect to landform in a manner that the streets allow to drain the rain water during monsoon. They depend upon forest produce for their livelihood. [1]Unlike the tribes living in plain areas. their dwellings are also scattered They live in clusters of three to four houses and even these clusters are at different levels away from each other because of undulating landform. These clusters are not connected by defined pathways as the houses are constructed in the fields itself, for example, village *Ufri.*

Figure 13 . Settlement pattern of a Gond village named “Ufri” according to the contours

Scattered settlement

The second type of settlement is comparatively smaller, the number of dwellings goes up to 30. These settlements are the satellite of the nucleolus village. They have a non-linear pattern of settlement. A group of 4- 6 houses are built together forming a place of social cohesion in the centre. But these houses also have the same concept of the backyard which is connected to the farms. As the family expands village becomes dense. Once the settlement reaches the maximum number of houses a new settlement in the vicinity is set up.

Figure-14. Scattered settlement of a Gond village named *"Bhagda"*

Compact Planning

These villages are located on plains and the average size of the village is 100-150 houses. This settlement acts as the nucleus for the small tribal settlements which are on the periphery at the distance from 2 to 10 km. The growth of village is organic and the distinct impression is made by the road which connects the village with other villages. The placement of the houses is more linear and compact. The connectivity of pathways is in accordance to the pedestrian that is why it has acute turnings and fewer junctions. [2]The pathways have houses on both sides with the same concept of backyard connecting the farms. For the social gathering, huge open spaces are left between the house lanes. This open space is multifunctional. It is the centre place where the market, fairs during festival and rituals are performed throughout the year. It is often known as "*Chupal*".

Figure-15. Compact settlement of Gond village named "Mahroi

Dwelling layout

From the study done on the Gond settlement, it is clear that these tribes make an effort in integrating the spatial, social and ritual perspectives and ultimately leading to a habitat which amply represents in their dwelling which varies depending upon the location, occupation, community and the micro-climate.

Dwelling plan

The house studied was a Gond farmer with 6 family members. This house has a rectangular plan with central courtyard used as a multipurpose space for all the day today activities. All the rooms are planned along the courtyard connected though a semi-open veranda. It is a free space which is used as a sleeping area and also for cooking and storing things. The entrance is an intricate welcoming semi- covered veranda called "*parchhi*" with black pillars supporting the roof used as a common interacting space where the neighbours or visitors gather. As we enter the house, there is an enclosure which is used for different purpose like keeping vehicle's, crop from farms and is also used as sleeping space for guests. The enclosure on the left side is semi-open is used as an animal yard. On the right, there is a kitchen, "*devlok*", space for the deity. ''*Kothi*' granary made of mud and straw is also used as a partition in living spaces. There are two rooms in the back-side of the house used as sleeping space.

Figure16. Elevation and Section

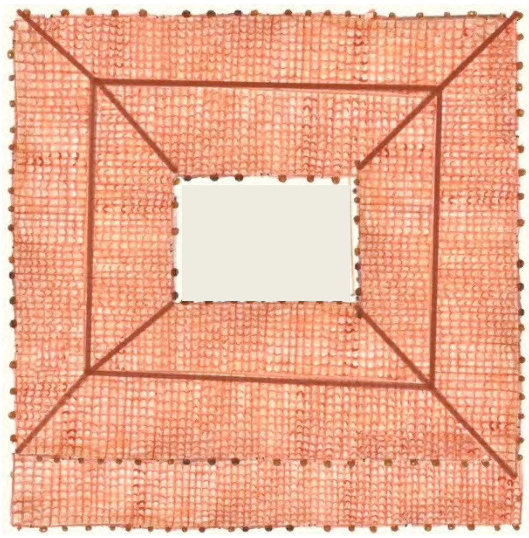

Figure17.Roof Plan

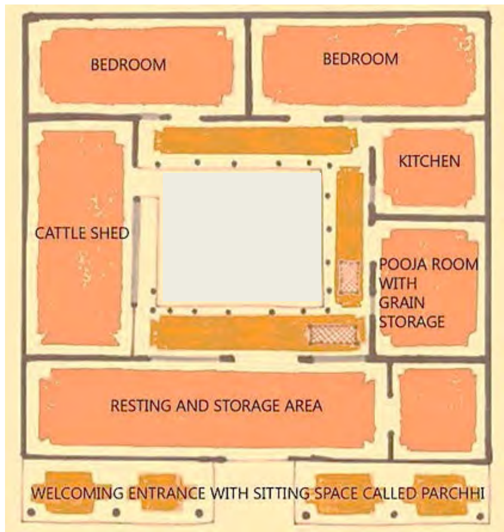

Figure18. Plan

The roof type is lean-to roof for semi-open space with supporting member of timber columns. The openings have door panels only on the external walls. For ventilation, small vents are provided on the external walls. There are no openings on side walls all windows open in the courtyard. Pitched roof covered with terracotta tiles. Reeds are used for partitions.

Figure19. Wooden post on pedestal

Figure20.Mud Wall

Figure21. Roof

Construction

The main building material used for constructing the load-bearing walls of the dwellings was Adobe, since mud is the most plentiful resource in the region. Adobe units are made of mud, which can be found on site, mixed with straw along with water. The wall is on an average 300mm thick and has small niches called *"aale"* used to keep *"diya"* (oil lamps) or other useful items. The walls also have inbuilt racks beautifully decorated with relief work. The walls are hand-plastered with same mixture of mud and husk used in adobe units. After hand plastering the walls, they are beautifully painted with different coloured clay- red, yellow ochre, white and black.

The roofs are hipped, double lean and lean-to roof. The roofing is done with terracotta tiles, which are good insulators also. The load-bearing walls support the roof frame placed above. The main horizontal member is of timber on which king post along with the whole truss rested. The Eaves of the roofs are projected along with the length of the house. This projection protects the erosion of mud wall during rains and also provides sunshade. The temporary structure for cattle is constructed with four wooden posts and thatch roof. The lintels are of timber planks or stone members. For ventilation, rectangular voids are left in the walls. Bamboos are used as grills in case of large openings. In veranda, the adobe units are laid to form inbuilt furniture which can be used for sitting or storage.

Though some variations in construction techniques were observed in different villages during the research, for example, the tribes in village *Chandiya*, use sun-dried bricks for construction of walls in their houses. The size of the brick is 3"x6"x12".

Aesthetics

The Gond tribes do not give much height to their building which reduces the traces of built-up area in the skyline. The doors and windows are beautified by painting using different coloured clay. Bold borders are painted along the walls and floor. Elaborated relief work done using clay enhances the aesthetic appeal of the house. They mostly use geometrical shapes like triangles, circles and squares which form beautiful patterns. Some other relief works also depict their life and nature. The houses are decorated with paintings depicting animals, birds, trees and folklores. The Gond tribes believe that a good image brings good luck. This inherent belief led them to decorate their houses and the floors with traditional motifs. The Gond pradhan tribes of Mandla district developed entirely a different painting style which is known as Gondi art transformed on papers and canvas.

Figure22. Outside Door

Figure23.Veranda

Figure24. Inside Door

Result and findings

Common features observed in the selected Gond settlement-:

1.) The settlements have the single resource of water which is a river, waterfall, spring or a community well. There is no provision of sewerage in those settlements. The wastewater is directed into the backyard.
2.) All the houses are facing the pathway and have a backyard or farm land. The pathways leading to the houses are in accordance to the contours, and they are undulating and haphazard. They are narrow and do not have lot of intersections.
3.) Gond Tribes follow different pattern within the same geographical location. This variation is mainly due to topography, microclimatic condition and their occupation.
4.) Gond paintings are an integral part of their culture in which they depict beauty of nature and observations from daily life. But no such paintings were seen there.
5.) Present day construction is not in synch with the vernacular architecture which the tribes practise.

Conclusion

The Gond tribes developed a symbiotic relationship with nature. The existence of tribes has become an important attribute for maintaining a balance in ecology. According to the development traits seen in the present sinerio there is an urgent need to change the methods. One must consider the ethics and methods the tribes have adopted for construction and strictly adhere to it. To maintain this system there is a need to understand the tribal way of living and provide appropriate planning and design using their knowledge .

Design to Thrive

THE ADOBE Educative video for a locale culture

Amanda Rivera Vidal[1,2], Cristian Muñoz[2]

[1] Escuela de Construcción ECoT, Santiago, Chile, amandariverav@gmail.com
[2] Rivera+Muñoz, Santiago, Chile, riveramunoz@gmail.com

Abstract: The educative video "THE ADOBE" is the result of a research made on the centre of Chile. It has been made after a large earthquake which took place the 28 February 2010 in the central zone of Chile. This zone is the most urbanized that concentrated 90% of the population of the country. This event has deeply marked the memory of the Chilean people. The video shows and highlights the knowledge of the inhabitants of this territory, and looks to strengthened a constructive culture: the technique of mud brick. In central Chile, a third of the population lives in earthen dwellings today. In Chile, the adobe brick is the most used technique of earthen construction. It is part of its heritage, its past and also its future. Although this material is very present in the landscape, it fell into disuse and oblivion. Unfortunately, its implementation remains the most stigmatized and the least studied.
The educational video so provides knowledge to combat this ignorance on the construction of adobe and promote this heritage. It is a manifesto to save this constructive culture.

Keywords: mud brick, heritage, earthquake, vernacular construction, Chile

Introduction

The adobe is one of the techniques that have accompanied the man from his sedentary settlement, which manifests itself in a universal way adapting to its conditions. The adobe, in its apparent simplicity, has existed for two millennia (Noriega & Vauzelle, 2014).

Chile has been founded on adobe constructions, being the union of the native technology with the culture brought by the Spanish conquerors that settled in the south of the American continent during century XVI, establishing the main urban centres "from the valleys of the *North Chico* and Concepción"(Benavides, 1988). This culture later expanded to the whole territory known today as Chile, from the North to the Patagonia.

Chile and the earthquakes

Chile is located at the south of South America, between the Pacific Ocean and the Andes Mountains, geographical limits that are the evidence of the confrontation of the tectonic plates that generate the recurrent seismic movements which characterize its culture. Chile is one of the most seismic countries in the world, where large earthquakes have occurred in the past and will certainly cause major earthquakes in the future (Barrientos, 2010).

Figure 1. House in the epicentre of the earthquake of 2010 (-35.951561, -72.743889), contrast between occupied, restored, maintained and neglected housing. Trehualemu (Chile), 2016.

The last earthquakes - 2005 of 7.8Mw in Iquique; 2007 of 7.7 Mw in Tocopilla; 2010 of 8.8Mw in Cauquenes; 2014 of 8.2Mw in Iquique; And 2015 of 8.4Mw in Coquimbo - that have affected Chile have struck large areas of territory, extensive and traditionally built with raw earth blocks. Although there is no accurate data on the amount of adobe buildings or, therefore, on the percentages of adobe dwellings damaged by these earthquakes, it is estimated, according to data from the Inventory of Cultural Heritage Property prepared by the Architecture Department of the Ministry of Public Works, that about 40% of the official heritage declared sites are built on earthen techniques predominating the raw earth masonry and the mixed techniques of wood and earth (Contreras et al, 2011).

After each event, there has been a lack of knowledge about traditional constructive cultures, which are adapted to the central characteristic of the territory: earthquakes. Although in the Chilean territory the immense majority of the heritage constructions is built in adobe the knowledge of professionals, both their existence and technical-constructive specifications are few. Even if the oldest building of the colonial time: the church and convent of San Francisco located in the main avenue of the capital Santiago, not to mention the immense amount of vernacular heritage scattered throughout the territory, are built with mud brick.

In spite of the growing interest of professionals for the earthen construction and technologies, the wide presence of contemporary constructions with the material and the nascent activities of diffusion of these material in the country; as well as different initiatives at the international level to promote earthen construction, recognizing that earth has been, is and will be one of the main materials used by mankind to build their habitat and shape their habitat, and that at least a quarter of the world population lives today in earthen houses (World Crongress TERRA, 2016). There is a systematic marginalization of the study on the traditional and vernacular technologies that have built the Chilean identity, which has generated not only a generalized ignorance in the national professionals, but also a stigmatization and widespread rejection towards the old constructions, thus forgetting the traditional technologies that, through the trial and error of centuries, have mixed native technologies with a Spanish foreign technique adapting it to the Chilean seismic territory through various strategies and intelligences (Figure 1).

Earthen constructive typologies

From north to south of a country with 4329 km length, there are different expressions of popular earthen architecture. In the arid north of Chile, where stone, earth and cactus are the only building materials, earthquake resistant strategies are based on the geometry of buildings. In the central and southern regions, where temperate and cold climates allow the growth of large trees, wood reinforcements are the most frequent earthquake resistant solutions (Jorquera & Pereira, 2015), demonstrating the adaptation of the culture to geographical diversity.

The different earthen techniques are rather mixed constructions, where the earth together with other structural elements, like the wood, compose the constructive system; or only earth techniques, such as mud brick and rammed earth, where the structural element is the earth (Muñoz & Rivera, 2012)

Mixed constructions earth and wood

The large quantity of wood transported aboard ships in the northern hemisphere during the 19th century resulted in the creation of a wooden carrier system filled with blocks of land called "adobillo" (Jorquera & Pereira, 2015). This system is delivered with all its splendour in the hills of the city of Valparaiso. It is a prefabricated system mainly generated by the abundance of soil suitable for the execution of the earthen blocks, but not at the same place of the port but on the hind slopes. Thus a method to fabricate smaller blocks (50x15x10 cm) was created to facilitate transport. This system consists in anchoring the earth blocks to the wooden support structure thanks to the shape of the block which prevents the movement of the blocks at the dynamic moment from the plane of the wall. It is essential that the blocks are anchored on both sides of the wooden structure (Figure 2a).

This system is replicated in different parts of the country with some variations, incorporating appliances and mortar between the blocks, which allow the separation of the vertical structure. It is generally used as the secondary structure in adobe constructions.

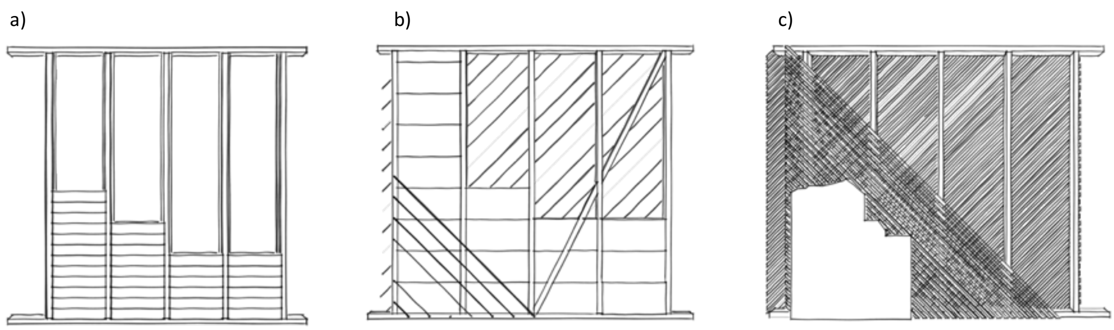

Figure 2. Traditional mixed earth and wood constructions: "adobillo", "pandereta de adobe" and "quincha"

As a complementary system and commonly found as a secondary structure of adobe constructions there is the constructive system called "*pandereta*" or "*adobe parado*" because of the use of the same adobe block, usually 60x30x10 cm, placed on edge (Figure 2b). This typology is still found as a secondary structure for filling a wooden supporting structure to which the blocks are not anchored, but bonded by steel wires and less frequently by wooden slats. This system is used recursively to make internal divisions or floors. Traditionally, its structural logic compels it to be separated horizontally by wooden pillars, in order to avoid the weaknesses of the disunity of the blocks (Rivera, 2016).

The seismic and native construction system for excellence in this field is the "*quincha*", the quechua[1] name for the wattle and daub technique (Figure 2c); when in a territory with abundant plant resources. This works with different woods as a primary and secondary structure, abundant in the second elements of the materials of least resistance such as the branches or minor section bamboo. This system of construction is not limited to the humble constructions of indigenous peoples, but has been reproduced and used in constructions of Hispanic influence, mainly in the port cities. It was used in the first towns of the territory when it was the local workers who built "we made our wooden and straw houses in the track that gave them" (Benavides, 1988).

Earthen massive constructions

The rammed earth and *adobón*[2] are two systems of construction in earth mass that is mainly like a delimitation of the land or the habitat for the animals. It is used in some northern cultures to build human dwellings but is more used as exterior boundary. Both are manufactured in the site and in its final location, with a thickness around 50cm or more. The difference between them is the consistence of the filling mixture, the firs one uses a humid mixture and the second a plastic one, thus with more water on it. In these systems, there is a necessary overlap between the blocks (Rivera, 2016).

The construction system par excellence found in the foundation of the towns and villages is the adobe. Over time and nearly 500 years since its implementation, it has incorporated different strategies, to try to circumvent the problems associated with earthquakes.

EL ADOBE, the mud brick

The adobe is a raw earth block formed by hand or moulded in plastic state, and then dried in the air. Compared with other earth-building techniques, brick masonry is synonymous with a very fast execution, comparable to that provided by industrial materials. The adobe is extremely economical, even in developing countries, where blocks and construction are almost tool-free (Anger & Fontaine, 2009).

The construction in adobe is a universal system, which in Chile is expressed with proven seismic components, is the sample of an evolution in the resolution of problems of sustainability and construction pertinent with the local environment and culture. It is a system not only suitable for heritage, but also for sustainability and the future, and has been tested against the earthquakes of greater magnitude of the planet. The adobe, is the ductile instrument of the whole peasant construction, based on the empirical handling of the behaviour of the materials in front of the earthquakes.

It is observed in traditional architecture that for the correct behaviour of simple masonry structures there are a series of rules that buildings which have already undergone several earthquakes. This represents the state of the art and it is essential to give importance to the complete structural analysis of constructions. The geometry of the buildings reveals that the main requirement is that buildings should be simple for greater seismic stability. The building must have symmetry in terms of mass and rigidity, both in plan and elevation, to

[1] Native South American language family spoken primarily in the Andes
[2] Known as a big adobe build on site

reduce torsional stresses; a slight slenderness, in order to reduce the tendency to tilt; and a compact plane with a low ratio of height and length, to have similar resistances in each direction. Homogeneous façades with floors of the same height and a low centre of gravity can also reduce the vulnerability of the building. The number of openings should be reduced, carefully and symmetrically distributed (Correia et al, 2015). Each strategy exists with its own intelligence and technological development of a given moment, which progresses and evolves towards the best resolution of the generated problem, for stability in the face of earthquakes. The strategies are complementary and crossing them represents a behaviour far superior to the movement.

Along the Chilean territory, that covers 4,000 kilometres (2,500 miles), different adobe cultures emerge, according each one to the local resources, the cultural influences and the natural environment. At the north, where vegetation is rare, the structural performance is based on the mass strategy (Figure 3a). This gives great importance to the thickness of the wall. The adobe construction has a minimum slenderness radio of 1:8, making the traditional walls at least 50cm thick. In spite of that, walls of 60cm are are the most frequent, because the most common raw block measure is 60x30x10 cm (236”x118”x39”) where its length becomes the thickness of the wall. At greater heights, the walls increase to 90cm (354”), 120cm (472”) and up to 150cm (590”) thick, measures that arise from the modulation of block (Figure 4).

Another structural strategy present un the country are the counterforts, that are external wall elements that support them and counteract the seismic efforts. They avoid the walls overturns and give the stability. They are used mainly on churches, where there is a great wall length with a lack of interior support elements (Figure 3a).

a) b) c)

Figure 3. Different adobe cultures from the north to the south as a demonstration of its context. Pachama Church in the Atacama Desert, a house in Petorca in the central zone and a house in Puerto Guadal in the Patagonia.

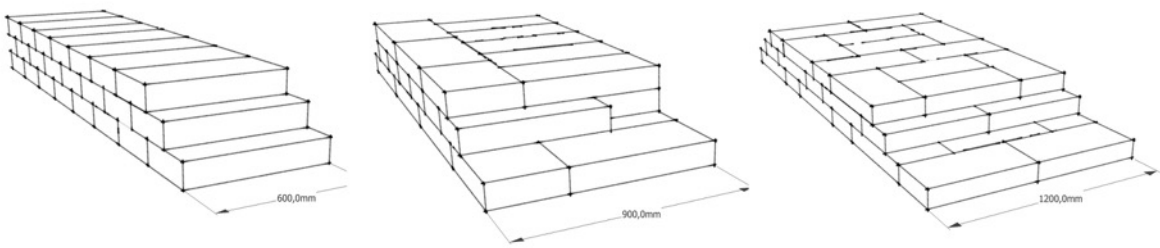

Figure 4. Different raw brick rigs with 60x30x10cm block. 60cm, 90 cm and 120 cm of thickness of the wall.

In the central zone of the country, from the zone of the “Norte Chico” until de Bio-Bio river, their is a culture of wooden reinforcement which help adobe constructions with the dynamic moment, because of is flexibility, lightness and deformability without reaching breaking point. These reinforcements are horizontal wooden, placed along the construction as horizontal ladders called "*llaves*" (Figure 3b) or in critical zones such as the join of two walls called "*esquineros".*

One of the newest abode cultures of the country is the austral one, which began 100 years ago, when some northern communities arrive to this lands. In this zone, because of the lack of earthquakes, the seismic parameters are absent. The adobe constructions are mixed with wooden roofs (Figure 3c), being the mixture of the abundant elements available in the territory (Jorquera & Rivera, 2015).

Educational Tool

To re-educate about the ancestral and more massive construction system of Chile is the main objective of the educational tool, which is expressed in the form of video to expand the audience to which it is wanted, becoming an instrument easily accessible and understanding. Destined to builders, authorities, academics, professionals and the inhabitants of adobe houses, it aims to re-educate, especially to build and understand the adobe constructions.

Building in adobe should be an integral exercise: understanding, restoration, reinforcement, completion, maintenance, reconstruction and habitat should be understood as a whole, to ensure its endurance in time and adequacy to contemporary needs properly. Despite the enormous number of examples of adobe buildings compatible with the largest earthquakes in the world, national information and studies are scarce; So the work begins with the premise of finding information from the same terrain: buildings and builders. The development of educational initiatives in the area affected by the earthquake of February 2010 has since been the main work of the team; Repairing, training and valuing local knowledge and materials. And it was there that can rescue the main amount of information for the construction of an effective educational tool and layers to disseminate and value constructive technique through the delivery of tools for its repair and reuse (Figure 5).

Foreign reparation experiences are taken, such as the investigations of the Pontifical Catholic University of Peru and its application to the Chilean case through electro welded meshes. But above all, it seeks to put in value the health and constructive intelligence of traditional adobe systems, which, based on three basic elements (earth, straw and water), have faced great movements and changes.

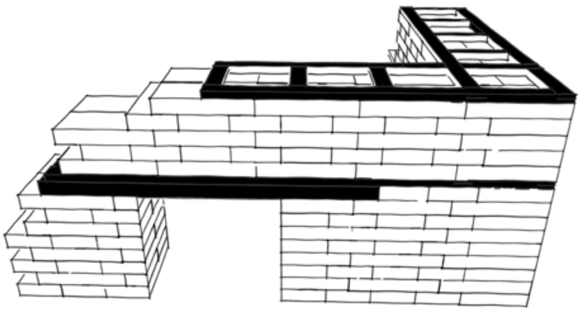

Figure 5. Illustrations of the educational video. Explanation of the incorporation of wood elements to the masonry of raw earth.

Educational video

The educational video "EL ADOBE" is the result of research conducted mainly in central Chile after the earthquake that affected this area in 2010. The audio-visual document is focused on adobe construction and seeks to represent constructive culture local of this territory, with its knowledge and constructions. Systematizes experiences, seeks to promote as a viable alternative the repair of adobe constructions and socialize the knowledge about techniques suitable for their care and maintenance. It is an educational tool of wide scope of geographical and temporary way; Transporting in a faithful way what happened in reality.

The video begins with the Chilean national context of construction in adobe, making a concise tour of the territory evidencing the presence of the material in cities and towns. Then it goes into the technical narrative by transforming this cultural route into its constructive manifestation: Chile's different earthen building techniques, their differences and structures, is where it focuses on Chile's most massive technique: on the construction in adobe. The story begins with the manufacture of the raw earth block: its materials, forms of realization and measures; to continue with the way of arranging these blocks for the creation of spaces: the masonry of adobe. To help the current reality of construction in adobe, the most frequently encountered damages are posed and then possible repairs; always contextualized in the Chilean reality and its seismic context. The video was developed with the main support of different professionals with extensive experience in the construction and repair of raw masonry. And it was developed jointly with the Rivera+Muñoz producer, the Jofré Foundation and financed by the National Council of Culture and the Arts (Ministry of Culture).

Figure 6. Exhibitions of the video in cities and towns affected by the 2015 earthquake on the northern of Chile. Canela 2015 and Combarbalá 2016.

Dissemination and implementation

After the realization of the educational video from the year 2010 to 2012, a diffusion was made in different networks, mainly between academics and professionals. Distinguishing between them the cycle of presentations made in 2013 to six universities from Iquique to Concepción. After that the main tool of diffusion has been through the internet where the video can be seen and download, which already has more than 13 thousand reproductions since its launch in 2015, which demonstrates the interest in acquiring knowledge in this subject.

Despite the enthusiasm of the authors for the massive diffusion of the information and therefore their complete openness to the use of the material, it was only until after the earthquake of Coquimbo of September of 2015 that it was verified the usefulness of the tool, as a method of easy transfer of information. The projection of the video, first in the square of Canela (the epicentre of the earthquake) was the opening to deliver knowledge both to professionals and local inhabitants, who have used the knowledge delivered for the development of repair and rebuilding of the affected area. Then the replication of this activity in different communities of the region (Figure 6) has had a large and important impact, where copies have been distributed massively, where the message has been transferred and used.

Lessons from the Shikumen of Shanghai

Rachel Simmonds [1]

[1] Interior Design, School of Design, University of Edinburgh, Edinburgh College of Art, rachel.simmonds@ed.ac.uk

Abstract: This paper looks at the Shikumen housing in Shanghai, and explores the aspects of its unique character that can inform design to form, support and retain communities in today's expanding urban landscape. Unique to Shanghai, the Shikumen, built in the mid 19th Century, were speculative developments housing workers. Their layout, of a main alley with branch alleys off, formed city blocks and communities. Their typology, signified by the stone gate entrance, inner courtyards and hierarchy of internal spaces, created communities within communities. With the development boom in Shanghai, the Shikumen are being demolished. Some have been retained, but mostly in a pastiche form that supports non housing uses such as shops and restaurants. Only recently has the importance of their original function within families, communities and the wider city been realised. This is not being supported by any programme of retention or preservation. This paper will analyse the Shikumen to extract those important elements that are relevant to the development of Shanghai, and housing on an international scale. It will make a comparison with the Colonies housing in Edinburgh, housing of similar form and age, that has not only been retained, but is being reproduced in a modern form.

Keywords: Shikumen, Colonies, Housing, Communities

Introduction

In 1842 the Treaty of Nanjing turned Shanghai into a treaty port. As it opened to trade from foreign countries, concessions began to be formed in the city to house the British, Americans and other Europeans living there. The Taiping Rebellion of 1850-64, resulted in refugee from the countryside moving to Shanghai, dramatically increasing the number of people living in the foreign concessions. This population explosion resulted "in the need for new accommodation and a new housing type, the alleyway house was developed to cater for this need" (Bracken: 2014). This emerging new housing typology is commonly known as Shikumen. The translation of the word is stone gate, and refers to the distinctive architectural entrance feature of the houses. They were originally commissioned and owned by foreign investors and have been described as being formed from "hybrid architectural styles that testify to Shanghai's unique history of colonial capitalism, industrialisation and cosmopolitanism "(Li: 2014). They were built from 1870 – 1940, and this paper deals with those from 1870-1910, known as the old style stone gate Shikumen (Bracken: 2012). It should be noted that these "foreign real estate owners relied on Chinese compradors to supervise Chinese contractors and manage the construction and rental of their properties "(Liang: 2008). There is "little evidence to support the view that the alleyway house is a hybrid of Eastern and Western building traditions", and that the builders of the Shikumen “may have copied some western details but that is as far as this hybridity goes. (Their) genesis is clearly Chinese “(Bracken: 2013).

There are however, typological similarities between the Shikumen and a housing typology in Edinburgh of the same era. So whilst they were not a direct influence on each other, how they have evolved over the past 150 years, highlights key elements that should be considered in lessons to inform design that forms, support and retain communities in today’s expanding urban landscape.

Elemental Analysis of the Shikumen urban block

It is important to understand their wider urban importance, before looking at aspects of the houses themselves. Shikumen were built in terraces, usually running east to west, with the main entrance to the house on the south side, with the secondary kitchen entrance on the north side. These rows form a series of secondary alley ways (approximately 3m wide), all of which run perpendicular to the main alley (approximately 4-5m wide). The houses to the perimeter of these lanes enclose it, thus forming an urban block. A typical block can contain around 100 houses (Bracken:2013). Entrance into the block is via one or a series of metal gates on the perimeter. These are typically open during the day but locked at night. The buildings forming the boundary tend to have shops on their ground floor and face out towards the surrounding streets. This protective barrier for the housing inside embeds the block within the wider urban context, and encourages engagement with the perimeter shops by those living out with the immediate community.

This creates an urban typography that supports a hierarchical series of spaces moving from public (surrounding streets), semi-public (main alley), semi-private (secondary alleys) and private (Shikumen themselves, including their courtyards).

Figure 1. Typical Shikumen Lane, Shanghai (photo: R.Simmonds)

Elemental Analysis of the Shikumen House

A typical Shikumen house from the mid 1880’s – circa 1915 is a two storey courtyard house, entered via a wooden door in a large stone gateway in the external wall. Passing through the gate you immediately are in a small courtyard. From here you enter directly into the sitting room of the house. This is where guests are welcomed and main family events take place. Leading off from each side of the sitting room are the wing rooms. One would have been used as the study for the man of the house, the other as a bedroom for the grandparents. When Shikumen were first built they housed a multi-generational family group, which was key to their success in supporting and retaining the communities they formed. Behind these is the stair to the first floor, and behind that a kitchen with small courtyard and stores. Above the kitchen, off the half landing of the stair is a small bed room, sometimes referred to as the garret (Zhang: 2011) or the tingzijian (Shanghai Xiantiandi). It was often rented out to a non-family member such as a scholar. On the second floor are the remaining family bedrooms for parents and children. This layout maximises habitable space by focusing circulation to a core at the centre of the house.

From 1870, they were typically constructed of masonry and timber, following the prohibition of completely wooden houses by the Shanghai Municipal Council (Zheng: 2011). The exterior walls are brick, sometimes with a white wash or cement covering. The gable walls to the main lane are often ornate and highly decorated. The key feature of the stone gate had ornate pediments and sides. The double leaf wooden door that sits within it is traditionally painted black and has large iron or bronze ring handles on each leaf. The roofs are terracotta pan tiled. All windows are timber framed and single glazed, with those looking into the courtyard being full height, often with semi ornate timber tracery. Exterior windows to the north and south elevations have slatted shutters. Each house therefore is dual aspect, but with a clearly defined front and back.

Internally the courtyard serves the dual purpose of improving ventilation in the house, and bringing light in to the interior. The internal staircase is timber, as are the screens that divide the wing and upper rooms, or form wall panelling in key rooms such as the sitting room (Sheng:2011). The internal walls were painted white.

Factors Influencing the Decline of the Shikumen

The decline of the Shikumen has been due to several factors. On 01 October 1949 China became a communist country. The Shikumen came under state possession and became collective property (Li: 2014). The communist government distributed the Shikumen to people for low rent. This resulted in up to seven families being housed in accommodation that had previously only contained one family. The low rent also meant that there was no money for maintenance, and the houses began to fall into disrepair (Tsai: 2008). The removal of owner occupier status also contributed to this decline as there was no one directly responsible for maintenance living in the house.

Due to their compact urban typology there was little flexibility in terms of expansion (Bracken: 2013). Whilst internally rooms could be reconfigured, there were limits due to the number of people now living there. Subsequently the lack of proper bathroom facilities became a much larger issue. Today the majority of Shikumen remain subdivided to house several families or groups, resulting in insanitary conditions. There are no internal toilets or washing facilities. These are catered for in communal blocks near the perimeter gates.

Construction of Shikumen ceased after the rise of Communism in 1949. At that time there were over 9,000 clusters of them in Shanghai, housing around 4 million people (approximately 80% of the population). Demolition began in the 1990's, and "as land values in central areas continue(d) to soar, whole city blocks (were) earmarked for redevelopment and the people who lived in them (found) themselves forced to move out "(Bracken: 2013). This again removed large amounts of Shikumen from the urban typology. Today its estimated that only around 200,000 people in Shanghai live in Shikumen (Grescoe: 2017), which equates to around 1% of the population.

Conservation of the Shikumen

In 1988, the non-gratuitous transfer of land use rights came into effect in China. Cities like Shanghai got very involved in urban redevelopment, (Yang & Chang: 2007). Unfortunately, a robust conservation policy was not equally established. In 1991 the Shanghai Municipal People's Government issued measures for the preservation of historic buildings in the city that divided them into three categories: nationally important cultural relics, cultural relics of Shanghai City and historic buildings of Shanghai city. This was slow to recognise the Shikumen. It wasn't until 2003 that the first local law for historic heritage preservation, The Preservation Regulations of Historic and Cultural Districts and Historic Buildings in Shanghai City was created. (Tsai: 2008). Unfortunately, "resolving the conflict between development and preservation presents a large challenge, especially when the historic significance of historic heritage is not well understood and the power of investing capital is predominant. (Tsai: 2008).

In the late 1990's, the 52-hectare site, known as Xiantiandi, in the city's Taipingqiao area, was redeveloped by the Luwan District Government and some Hong Kong based developers (Yang & Chang: 2007). It redeveloped the Shikumen in the block by retaining their facades and putting high end western focused shops and restaurants behind. Whilst the urban form is retained, it could be argued that the real spirit of the Shikumen has been lost, and in its place a pastiche idea of historic Shanghai remains, that gives a false impression of the hundreds of thousands of visitors, as to what historic communities in Shanghai really are.

Figure 2. Xiantiandi, Shanghai (photo: R.Simmonds)

In relation to the Shikumen the development of Xiantiandi is significant, as it recognised for the first time, the importance of the typology. A few other areas have followed a similar fate with an hotel complex created in one and the Tianzifang area focusing on tourist shops, restaurants and creative workplaces. Cite Bourgogne is the arguably the best example of Shikumen housing being retained, however its preservation and restoration is not to a level that would be recognised in the west as being protected or restored in any significant way, as they are still housing multiple families in poor condition.

The nature of historical preservation in Shanghai is highly pragmatic. Historical architecture is preserved not for its value as cultural heritage, but for the potential economic return. (Ren: 2008).

Background to Colonies Housing in Edinburgh

In 1861 the Edinburgh Cooperative Building Company(EHBC) was formed. Its purpose was to "get working men self-contained houses, where they would have their own front door, every room being independent of the other having a door from the lobby for privacy, and having little green attached to each house, and having everything arranged in a sanitary way" (Pipes: 1998). The first were built in Stockbridge between 1861-1911, on a rural site by the Water of Leith to the North west of the city centre. Known as Colony housing, due to their purpose of forming a community, this housing style is distinct to Edinburgh. There were 11 sites developed in the city by the EHBC from 1861 until 1946, when it ceases trading. (Rodger: 1999). When they were first constructed they attracted artisans and workers. Whilst owned by locals, initial figures suggest that 20% of the occupants were from Edinburgh, with the rest migrants into the city. For their size they were densely populated, with 13% having 8 or more occupants. Owners supplemented their incomes through lodgers, but this led to obvious pressure on space. (Rodger:2011).

Elemental Analysis of Colonies Housing in Edinburgh

The urban typology of the Colonies is one of city blocks formed from "tightly packed panel rows of houses with external balcony access to upper floors" (Rodger: 2011). The houses in each terrace are two storeys high, but the ground floor and first floor properties are accessed from neighbouring streets. This gives each its own private garden area. The upper floor properties are accessed by external stone stairs, with two neighbouring doors sharing an access stair and entrance balcony.

Figure 3. Typical Colonies Street, Stockbridge, Edinburgh (photo: R.Simmonds)

Externally, like most of Edinburgh, they are constructed from sandstone. They have a traditional Scottish pitched slate roof, with simple pitch gable at each end. The main doors are painted raised and fielded style, with a square fanlight above. Each one has a brass letter box and knob. All the windows are single glazed sash and case.

Internally the ground floor flats have a simple layout with a parlour to the front and a kitchen with separate bedroom off to the rear. The kitchen has a sink in the window and also contained a bed recess. The short hall that runs to the kitchen from the front door also has an inside wc and a coal store. The two storey upper colonies flats had a similar layout on their lower floor, but the wc moved to the location of the coal store to allow a stair to the upper floor to be inserted. The sink in the kitchen was relocated to a cupboard off the kitchen. On the upper floor are two bedrooms with former windows to the front elevation.

Conservation of Colonies Housing in Edinburgh

Today the Colonies are listed buildings, with those in Stockbridge obtaining a Category B listing in 1973. This means they are of national significance and any alterations to them required statutory consent.

Whilst initially these houses were home to large family groups, or a mix of home owners and tenants, by the turn of the 20th century things were beginning to change. The original residents had died and those that inherited the original houses did not necessarily stay in them. Today the Colonies are inhabited in a much less dense way. Throughout the city, and particularly in Stockbridge, these houses are now generally home to couples or small family groups. The original community created may well be long gone, but a new urban community is created, largely due to the close proximity of the houses and streets, and the middle class nature of the inhabitants. Stockbridge Colonies, has its own Residents Association, with its own website containing information for new residents and host of activities for residents to engage with. This community interest in their topology has been significant in preserving their form.

Similarities between the Shikumen and Colonies

There are a number of similarities between the two housing types that can be noted. The key one is that their urban form maximises available area by forming a series of tightly packed terraces. The plan of the houses allows for dual aspect, cross ventilation and defined private outdoor space. This hierarchy of public and private spaces is important in defining a community and both integrating and defining it within the wider urban topology. Removing, or in the case of the colonies reducing, the impact of the car on a pre-car typology, has ensured that people can move freely between properties, further supporting community activity and engagement.

A compact plan with minimal corridor space allows for easy movement between rooms, and supports flexibility in how the internal spaces are used, allowing them to accommodate varying numbers of people. Having a defined front door for each residence supports their individuality within the wider density of the urban form. The use of traditional materials ensures that the houses have the potential to be durable, as long as they are regularly maintained.

Both have supported a change between smaller family groups to larger multi family groups, although in the case of the Shikumen it is in the opposite direction to the Colonies, thereby creating more issues for the housing type, as the aging buildings have to tackle more physical demands by the numbers of inhabitants.

Lessons to be learnt on conservation from the Colonies.

The colonies can be considered to have survived for a number of reasons. Their urban density allows for a relatively large number of people to live in close proximity without feeling overcrowded. This is achieved by the splitting of the entrances for lower and upper flats to adjacent streets, thus allowing each property to have its own front door and defined outdoor space. These spaces are green, unlike the Shikumen where courtyards are hard landscapes.

Their construction is important. They were built well of good quality materials such as stone and slate. This has meant that they are hard wearing and, as most of the materials are local to the area or Scotland, can be replaced easily if required. Also their layout allowed for good in-house sanitation for washing and cooking. Whilst the layout was well considered, it allowed relatively large numbers of people to be housed in them initially, and has needed no major changes to support the smaller demographic who live in them today. The fact that there are two sizes of Colonies houses within the same development is also significant as it allows people to stay in the same area as their housing needs expand and contract throughout their lives, something now missing in the Shikumen with the loss of multi-generational family groups under one roof. The communities that they formed were strong and have survived. Today in the Stockbridge Colonies there is support for engaging with neighbours and those out with the immediate family group. Social status of these inhabitants support this, and for the Shikumen if they became aspirational houses then their value would increase dramatically.

Lastly differences in the national conservation policies as noted previously, and the current socio economic status of Shikumen and Colonies has had a direct influence on their differing heritage preservation.

To undertake and support any of the above, in the relation to the Shikumen, then recognition by the Chinese Government of their importance, back up by actual legislation and enforcement of conservation policies, with ensure the sustainability of these unique housing types. It is interesting to see in Edinburgh, over the last 18 years, a series of “Colony Style” housing has begun to appear as a new typology. Most significant of these are the Dublin Street Lane development by Richard Murphy Architects (1999), and the McDonald Place Development by EMA (2016). These new colonies are successful for a number of reasons including creating a sense of community which comes from sharing footpaths, gates and external stairs, use of traditional building materials, having larger windows openings and glass balustrade that give a contemporary feel and restricting vehicular access within the site (Urban Realm: 2015). The evolution of the housing form has not happened with the Shikumen to the same extent as their preservation has not extended beyond the shell of the buildings. Once you significantly alter the interior, especially the general massing, the whole functionality of the building, as a dwelling, is lost.

Conclusions

This paper has reviewed possible ways to conserve the Shikumen housing type in Shanghai, to ensure it plays a positive role in the urban expansion of this vast city. Its historic importance in the city must not be lost, as that would to lose a key part of the city’s character. Whilst their importance has been recognised in recent years, the pastiche retention or reproduction of them, in areas such as Xintiandi, does not go far enough in preserving them in their original way – as communities centred around families.

To support them as housing they need to update elements such as kitchens and bathroom to ensure satisfactory sanitation. Ensuring the quality of the external shops will support more outsiders engaging with the blocks. Finally limiting numbers of inhabitants and supporting long term residency will ensure that these buildings are cared for. Given the growth of Shanghai and high land values of these sites, it is uncertain how much longer this housing typology will remain. We can only hope that these developers see how other cities, such as Edinburgh, have retained and developed important housing typologies, and support the application of these ideas on a scale suitable to their urban expansion.

PLEA 2017 EDINBURGH
Design to Thrive

A Potentiality Analysis of Vernacular Buildings of Purvanchal towards Contemporary Adaptation

Pranjal Raj Singh[1], Pratibha Patil[2]

[1,2] Department of Architecture and Planning, Visvesvaraya National Institute of Technology, Nagpur, Maharashtra, India.

Abstract: Purvanchal is a geographical and cultural region in the eastern part of Uttar Pradesh in northern India which enjoys a rich cultural heritage with its own architectural style, building techniques and materials. The vernacular houses from the region are built in accordance to the composite climate characterized by extreme summers, cold winters and a humid monsoon season while the cultural, economic and geographical factors act upon it as form modifiers. The approach involved into the design and construction of the vernacular buildings in the region can be further developed and used into contemporary design practices to obtain sustainable results. In this paper, several tangible parameters such as spatial configuration, aesthetic considerations, passive cooling, ventilation techniques, and intangible parameters like lifestyle modifications, functional and cultural aspects, of these Purvanchal houses are taken into consideration for study. A comprehensive review of these vernacular buildings in the unexplored region is carried out in a quest for eminent sustainable, functional and yet climate responsive features with possible application in the architecture of contemporary times. The region long is observing immense ongoing developments since the last decade, making it critical to look for measures in view of a responsible growth. In a nutshell, this study has been able to systematically lay down passive strategies and tools characteristic to the climate of Purvanchal, and in the ongoing trend of distorted and discontinuous architectural practice, the study should provide a driving force to architects and policy makers towards a more directed, sustainable and region specific development.

Keywords: Purvanchal, Climate responsive buildings, passive tools, lifestyle modifications.

Introduction

Architecture has existed even before architects did and a huge section of the society even today build their houses themselves. The vernacular architecture is functional, primitive, local and of domestic nature. The traditional knowledge of this kind of architecture is intuition based and is passed down the generations. Function plays a major role in deciding the form, materials and the construction techniques of these buildings and as these functions get more elaborate with time, modifications are made and continued given the flexibility and user centric nature of the vernacular buildings (King & Amos Rapoport, 1984). The vernacular is not associated with the tradition, the latter being of elite nature and more stringent and sophisticated. The vernacular house grows with the family and is open for additions and subtractions depending upon the requirements of the inhabitants and this flexible nature of the vernacular house make it resource efficient.

Buildings have a huge impact upon the environment given the rapid urbanisation in the developing countries. While the vernacular buildings are climate responsive and need based, the modern buildings replacing them are completely the opposite resulting into a surge in energy demands, lifestyle changes and urban heat island (UHI) effect. Hence, it is very important to look at the vernacular architecture for inspiration, imagery and climate responsive strategies appropriate for a particular context. This would help in bringing down the energy demands and would also conform to the lifestyles of the inhabitants. While the commercial “green” is rigid and irrespective of the context of the building, climate responsive or solar passive buildings are the best way to achieve energy efficiency (A. S. Dili, et al., 2010).

There is an enormous collection of literature available upon vernacular buildings, *Built to Meet Needs* (Oliver, 2006)*, Architecture without Architects* (Rudofsky, 1987) and *Encyclopedia of Vernacular Architecture of the World* (Oliver, 1997) being few of the prominent ones laying down examples of vernacular architecture all around the globe. However, there has been observed lack of documentation and study of vernacular buildings in the geographical region of Purvanchal which has its characterstic architecture style and hence a need was observed to fill this gap through this study. With critical regionalism taking advancement today, the architects of the region should have an idea of what exactly should be understood as vernacular to Purvanchal and only then would they be able to recreate the experience.

Purvanchal: geography and climate

Purvanchal is a geographical region in northern India in eastern part of Uttar Pradesh, surrounded by Nepal on the North, Bihar on the east, Madhya Pradesh on the south and Awadh region on the western side. The region has its characteristic culture, language, geography, climate and architecture with Varanasi, Allahabad and Gorakhpur being the three major cities in the region. The region lies in the planes and is characterised by its extreme climate. Purvanchal experiences cold winters and hot summers and that has been a major challenge for the people of the region.

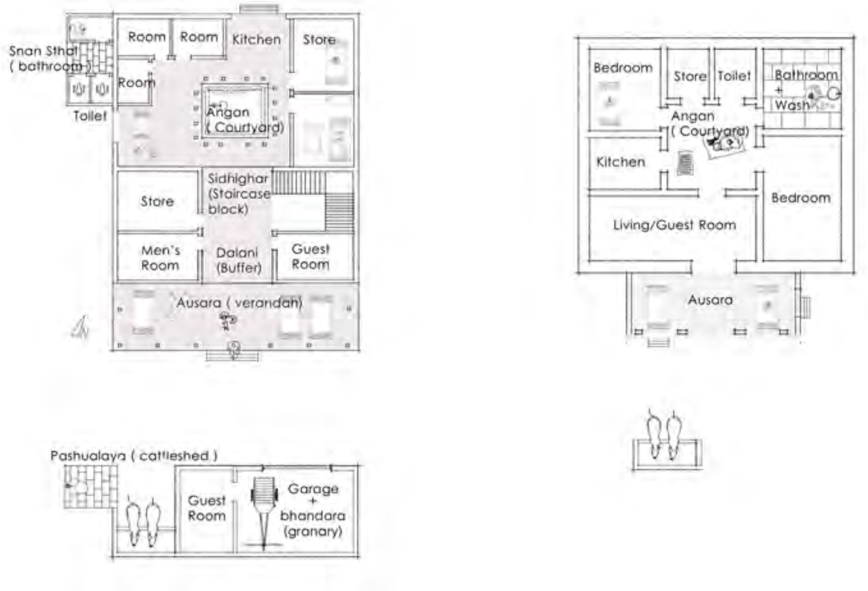
Figure 1 Figure 1: Purvanchal on the map of India

Research Methodology

The research aims at exploring and understanding the usual sustainable practices in the Vernacular buildings of Purvanchal, Uttar Pradesh by selecting, documenting and analysing few case studies from across the vernacular settlements of the region.

Description of selected sample of case study

The selected sample one is a 150 year old building made in mud and lies in the outskirts of Varanasi. The buildings walls are 0.8 to 1m thick made in mud with a clay tile roof on the top supported using a system of Timber and Bamboo girders. As seen in the plan in Figure 2(b) the house has thick external walls with an “Ausarsa” or verandah at the entrance acting as a congregational space for the men. The spaces are small given the thick walls and smaller span with a central courtyard which happens to be the major feature of every vernacular house in the region. The house belonged to a peasant with mediocre level of income.



(a) (b)

Figure 2 Plan of selected samples (a) Masonry house, Campiarganj ;(b) Mud house in Varanasi

The other case study done is a 70 years old masonry house constructed in a small village in Kunwar, Campiarganj (Figure 2(a)). The house is owned by a wealthy farmer family and hence boasts of a larger area with spacious activities. It could be observed that both, the mud and the masonry houses have a similar planning despite being different on the grounds by time, economy, city and material. In the recent past, houses made in brick and concrete were made with the traditional spatial planning and it is only now that it is being completely ignored over westernised house plans. Apart from climate, culture has been identified as a major form determinant for the vernacular buildings (Zare & Kazemian, 2014) and even in Purvanchal, this has been the case.

Traditional knowledge systems and climate mitigation

Traditional knowledge systems are developed as a response to its immediate environment in a way that it resonates with its cultural and traditional beliefs, ethnic values, resident’s desires and needs and the economic and social status of the inhabitants. This bank of wisdom is tried and tested sustaining the ravages of time and has been passed on through generation as a legacy of principles that determine the built response in present context. They play a pivotal role in spatial planning of the dwelling and show precedence over its zoning of activities and spaces.

Table 1. The table describes the activity analysis in relation to the time of the day for the masonry house

Type of space	Nature of space	Time	Activity	Users	Vernacular building practices
(Courtyard)	Private - (Acts as a focal point for multiple household and social activities.)	Morning up to 8 AM Noon from 11AM-3PM Evening 4PM–6PM Night 7PM-onwards	Morning chores like brushing, etc. Washing utensils, drying grains, afternoon nap Socialising and pre-preparation for cooking Washing utensils, sleeping	Everyone Women and children Women and children Women and children	• The courtyard acts as a heat sink in the day time and induces proper pressure differential air circulation. Presence of water source, further aids through evaporative cooling. • It also illuminates the interiors by allowing natural daylight inside.
Kotha (Terrace)	Private –	Noon from 11AM-3PM Night 7PM-onwards	For drying grains, food items, clothes, etc. For sleeping	Everyone Women and children	• The solar radiation falling on the roof's surface is utilized for household chore.
Ausara (verandah)	Semi-private- (Its a link connecting the private household spaces and the outside public areas.)	Morning up to 8 AM Noon from 11AM-3PM Evening 4PM–6PM Night 7PM-onwards	Socializing with neighbours Eating, afternoon nap Socializing, work, playing Sleeping	Everyone Men and kids Men and kids Men and kids	• It acts as a buffer space between the main road and the house which disallows direct sunlight to penetrate inside.
Bhandara (granary)	Semi- private	-	Used for storing grains and other agricultural products, equipment, tools etc.	Mostly men	• It is located away from the main building to disallow contact of moisture and for ease of external access.
Pashualaya (cattle-shed)	Semi- private	-	Utilized for housing cattle	Everyone	• Also, located away from the main building to maintain hygiene, proper comfort conditions for the animals and ease of access.
Dalani (buffer passage)	Semi-private (Utilized as a security feature to put a check on users entering the private zone.		Utilized as guest rooms and/or storage area	Everyone	• Acts as a transition space between the private courtyard zones to the semiprivate living space.

Accordingly, the structure is planned to orient its longer span along the north-south directional axis, in a way that the shortest side faces the southern direction and thus, reduce the direct heat gain due to harsh southern sun. The organization of spaces accommodates different levels of privacy with controlled accessibility and visibility. The interior dwelling spaces are arranged around the courtyard which acts as a focal point for the central organization and is graced by a holi *tulsi* plant in the centre. As air passes through the courtyard into the interior rooms spaces, it carries the sweet fragrance of the incense sticks from the *plant* along and perfumes the entire house. Washroom is placed in the northwest considering the prevailing wind direction so as to exhaust the odour away from the building. Similarly, *swayampak ghar* or kitchen is placed adjacent to the washroom area to ventilate the smoke arising from *chullha* or the stove, outside. Larger fenestrations of the private internal rooms open up into the *angan* (courtyard) and the *ausara* (front yard), against the small punctures that open up into the surrounding to regulate privacy. It also aids in avoiding direct heat gain into the interior spaces.

As agriculture is a major economic activity here, it necessitates the requirement of a granary or *bhandara*. It is detached away from the main dwelling unit to allow ease of external access while not compromising on the residents' privacy. It also checks and disallows the spread of moisture to the granary and helps it to maintain the favoured dry conditions. On the similar lines, the cattle sheds or *pashualaya* is not the part of the main building and is positioned away mainly for maintaining appropriate hygiene conditions and to allow ease of external access to the space without disturbance.

Climate mitigation techniques and approaches

A solar passive design for a dwelling is regulated in such a way that it efficiently uses the incident solar radiation for interior thermal comfort of the users, effectively warming up in the winters and cooling up in the summers along with generating ambient indoor illumination through natural daylight (Jayasudha 2014). Such a design has evolved as a necessity to achieve comfortable living conditions due to inaccessibility to the mechanized means of HVAC. The effectiveness of the climate responsive vernacular practices are explained based on the type of passive design tools and features incorporated and it's planning, the design of building components and related details used in a way to mitigate climatic features.

Courtyards as climate modifiers

Courtyard is a space in the house that is least affected by the annual, seasonal and diurnal weather changes (Figure 3 and 4). Courtyards have been generally referred to as a microclimate modifier in the house due to their ability to moderate high temperatures, channel breezes and adjust the degree of humidity, thus The level of thermal comfort in a courtyard space is determined by the microclimatic forces acting on it, most notably those of radiation and wind.(Das 2006)

Figure 3 and 4. The picture showing daylight penetration the courtyard of mud and masonry house

In case of both the houses, we observe effectively designed courtyards considering the optimum height to width ratio and overhangs are utilized to improve shading and the thick masonry/mud walls promotes thermal lag in the interior space. It has a water stack which keeps the courtyard floor wet and cool, thus, amplifying the cooling effect through the process of evaporative cooling in the interior spaces. Also, the presence of *tulsi* plant helps in achieving the state of thermal comfort further through evapo transpiration measures which also induces moisture in the air.

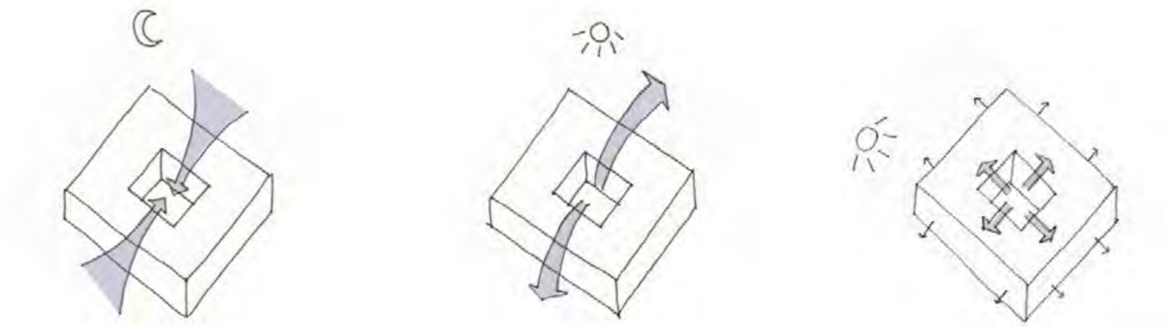


Figure 5: Climatic Implications of Courtyards (Desai, 2011)

Phase 1: Cool night air descends into courtyard and fills surrounding rooms, walls, floors, roofs and ceiling which become cooled and remain so until the late afternoon. Once the sun is up, the courtyard loses heat by radiating it to the sky.

Phase 2: Once the sun strikes the courtyard directly around noon, the cool air starts to rise and leak out of rooms through convection. With the outdoor temperature rising, wall thickness and material prevent heat to penetrate through walls.

Phase 3: In the late afternoon, the courtyard floor and the interior of the house become warmer allowing for convection and heat exchange with the cool interior air.(Figure 5) (Desai, 2011).

Adobe wall as thermal mass

Earth walls have proven to be better thermal insulators as compared to brick or cement concrete block walls (S. Goodhewa, 2005) ; Study performed by Shukla (A. Shukla, 2009) shows that earth has low embodied energy values along with low operational energy and transportation energy values as compared to modern construction materials. A Study

(Mohammed, 2004) further shows the effectiveness of earth in maintaining comfortable indoor thermal environment of houses in relation to outdoor environment.

The mud house is constructed of thick mud walls with the external walls of approximately 1 m width while the internal walls are of 0.8 m width. The walls act as heat absorbers during the day keeping the indoor environment cool and dissipate the heat at night, thereby, achieving thermal comfort through regulating heating and cooling conditions in the interiors. The high specific heat capacity induces such a behaviour which helps in high heat absorption. While adobe walls absorb heat, the courtyards enhance air circulation due differential pressure and temperature conditions; thus, integration of the two helps in achieving optimum thermal comfort conditions in the dwelling. Apart from the effective heat insulation, adobe walls act as effective sound insulators.

Fenestration design

Doors and windows are the only types of fenestrations in the selected case studies and are purposely kept minimum in size and number to disallow direct heat gain from the immediate surroundings (Figure 6 and 7).

The private spaces in the both the case studies have their larger windows opening into the central courtyard and front yard, while the external wall is punctured with small openings (Figure 6,7) for privacy, heat gain and lighting level controls. Apart from this, the above arrangement of fenestration aids in air circulation inside due to the venturi's effect .

Figure 6 and 7. Fenestrations into the walls of the mud house

Roof design

For the mud house, the sloping roof is one of the important climate responsive building components, which aids by reducing incident heat falling on the surface due to its angle of slope (30-35 degree) and reflecting the maximum amount of heat back. The roof height near ridge which is 4 m high, acts as a major insulation space and facilitates a good air flow inside. The roof has punctures to illuminate the interiors with natural daylight and to vent the warm air out of the space through stack effect.

Conclusion

It is observed that despite the extreme weather conditions in the region, the vernacular houses provide comfortable thermal conditions inside the house without being dependent upon any mechanical means for cooling or heating. Apart from the climate responsive design, the houses are built to suit in the culture and lifestyles of the people of Purvanchal. Non tangible and behavioural issues such as privacy and safety are very well addressed by translating it into the planning features such as *dalani* or a buffer space. The modern day architecture of Purvanchal evidently includes flat concrete roofs, closed and decentralised plans, large glass fenestrations and to further counter the adverse impact of these features, mechanised means are used. However these could be easily replaced with sloping clay tile roofing, centralised courtyards and smaller directly exposed openings and buffer spaces. The study reflects upon the possibility for architects to design buildings where people could live with minimal energy consumption just by designing with the primitive and area specific approach of a house and the comfort associated with it. Moreover it is architecture that could help to keep the visual as well as the cultural character of the region alive. While studying a vernacular building, the focus shouldn't be on what is built, but on what has been the process behind the final result. Learning from the folk architects their language of building, would enable the architects of the region to make more responsive architecture, in terms of , an individual, the society, and the environment on the whole .

Elements of sustainability of the Casbah of Algiers

Fatiha Talmatkadi[1,2]

[1] University Mouloud Mammeri, Department of Architecture, Tizi Ouzou, Algeria, fatihatalmatkadi@yahoo.fr
[2] VUDD Laboratory, Polytechnic School of Architecture and Urbanism (EPAU), Algiers, Algeria, kahinadjiar@yahoo.fr

Abstract: Thanks to the genius of its builders and the ingenuity of its managers, the CASBAH of Algiers has not ceased to fulfill its urban functions, and its economic and social development has not compromised the intergenerational profit for more than 900 years. Today it can be described as an avant-garde model of a sustainable city. The perimeter of the materially predefined city has favored growth by densification in opposition to urban sprawl. The exploitation of the renewable resources necessary for the survival of its inhabitants and its comfort, such as rainwater, sun and winds, have been the subject of systems elaborated with very ingenious rudimentary means combining between the urban structure Adapted from the city and bioclimatic architectural solutions. For the control of nuisances and pollution, a system of functional hierarchization is established, where harmful activities are rejected at the periphery of the city, with relative locations favorable to the neutralization of the pollution generated, and the noblest productions are concealed within the agglomeration. This environmental genius is reinforced by the establishment of a socio-urban system based on spatial hierarchy aimed at preserving cultural values and strengthen its social link between residents, and even social solidarity. This system enables the inhabitants to master and control each other's surroundings, a very effective means of maintaining intimacy, order and security within the neighbourhood unit, while ensuring a community life that is omnipresent at All scales of space. The organization of the city in neighbourhoods gives the autonomous management community, where "Amin" (tribal chief) played the role of intermediary between the population and the Center from Istanbul. A decentralization of power which promotes good governance. This brief reading of the elements that contributed to the sustainability of the Medina of Algiers clearly shows that the approaches related to sustainable development are ultimately only the reaffirmation of ancestral approaches.

Keywords: Casbah of Algiers, sustainable city, bioclimatic architecture, spatial hierarchy, governance.

Introduction

About a thousand years of age, can only testify to the sustainability of this city.

The Casbah of Algiers never ceases to charm artists, fascinate writers and amaze architects and urban planners until today.

"… She is unique. She has no equal. No other has at the same time this orientation, this position, this climate, this precise architecture ... " (Ravereau, 1989)

"... the Casbah gave me the exhilaration to contemplate a mirabilis urbs, a city of miracles testifying to the inexhaustible human capacity to create beauty and grandeur, ..." (Kennedy, 2013)

So many testimonies of great people can only arouse our curiosity to study and understand the peculiarities of this city, and the Indicators of its sustainability.

Sustainability Indicators

Integration with the site

The perfect integration with the site is one of the fundamental elements that has made the exceptional beauty of the city of the Casbah which melt beautifully into the mountains to which it is leaned in the background, At no time the builders of this city wanted to adapt the site to their work, it is rather the work that has adapted to it so respectfully.

The medina of Algiers extends over 45 ha with an average slope varying from 15% to 20%. It is bounded to the north and south by ridge lines, and punctuated by talwegs with slopes of up to 40%, allowing a one-storey shift between two adjacent houses. (Atelier Casbah, 1981)

The slope of the ground is exploited for the construction of shed for animals, independent of the residential function, or subsoil where aeration is ensured by an elevation of the house giving rise to a few intermediate steps between the street and the front door. (Missoum, 2003)

Figure2: Adaptation of constructions to site morphology

A city with a predefined perimeter, a densification factor

The historic city "Medina of Algiers" is naturally delimited by the sea to the east, and the massif of Bouzareah to the west. It is divided into two clearly distinct parts, one, high, residential, and the other, low, commercial and ramparts ensuring its protection against enemies.

The fixed perimeter of the city, did not constrain its growth, nevertheless, it has oriented its development. Instead of spreading out on the surface, once the soil is saturated within the ramparts, the city has developed in height, and it is in this process of densification that resides all the peculiarity of this Medina. In the 17th century we are already witnessing at the creation of the dense city in opposition to urban sprawl.

"... the city is gradually filling up) ... by tightening its road network, ... once the ground is saturated, climb up with an average (GF + 2) template ... We observe a very dense aggregate horizontally that can go as far as a common ownership on four sides of the house in the case of courtyard houses. " (Boughrira-Hadji, 2007)

The densification can spread on the streets, the extensions cover the street by overlapping at different levels in the neighboring houses, the overflowing spaces are called corbels.

Figure 3: Corbelling (for interior surface gains)

Passive comfort / Reduction in energy consumption

The densification

The densification of the city was a key factor in reducing energy consumption. Indeed, urban morphology plays a very important role in the creation of microclimates.

A dense urban fabric preserves the ambient temperatures of the interior spaces, hence the reduction in energy consumption. The device is purely passive, this urban density is obtained from the joining of the constructions to each other, which minimizes the walls in contact with the outside, hence the reduction of the losses of heat during the cold period, And the preservation of sunlight and the creation of shadows during the warm period. More the house is compact less it consumes the energy, the compactness is inversely proportional to the surface of the free walls (C = V / S). (Abdulac, 1982)

The ventilation

The orientation of the city ensures the supply of fresh air through the exploitation of the prevailing summer winds blowing from the northeast side. The capture of these winds is ensured by the implantation of the city perfectly transcribing the topography of the ground. In fact the alignment of the urban facades in parallel with the contour lines causes the movement of the fresh air streams inside the islands. The corbels contribute effectively to the moderation of the temperatures through the creation of the shadows at the level of the public passages. The freshness of the air is also preserved by the presence of public fountains at the level of the streets. As for the prevailing winter winds (north-west), the preservation of the city against these has found its solution both in the elevation of the site, whose massif of Bouzareah makes screen for these winds and reduces significantly their intensity, Than in the orientation of the buildings which give them back.

Figure 4 : Maitrise des vents par la morphologie urbaine

On the architectural plan, all the houses of the Casbah testify to the genius of their builders who were able to develop bioclimatic systems minutely elaborate, having greatly improved the conditions of comfort and well being of their inhabitants.

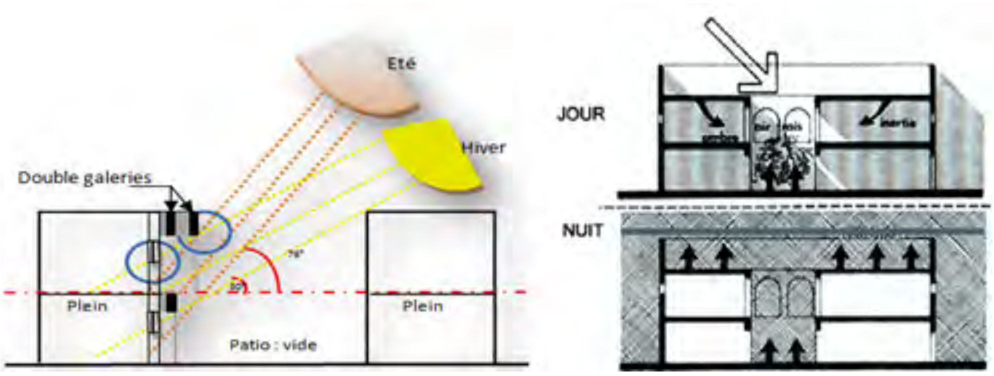

Figure: 5 Galleries and thermal comfort

The houses are equipped with a system of galleries whose depth is consciously reflected accordingly to the trajectory of the solar rays on the horizon line, these constitute a screen blocking their passage in summer , and vice versa in winter. The spaces of the houses most exposed to the sunshine, are sometimes endowed with two rows of gallery, even Dar Aziza and Dar Bakri.

The Comfort is also a matter of handling the stream of air. Indeed most houses have a patio called “wast-al-dar”, which plays the role of thermal regulator, the variation of the temperatures of the air between the inside and the outside creates differences of weight of this one, and this causes its movement. This phenomenon of ventilation is consolidated by another movement caused by the difference in height of the opposite openings in the same space, and the chimney facing the winds of summer (northeast). Moreover, the built-up envelope "... allows the building to benefit from close interior atmospheres Comfort for a wide range of variations in external conditions, without the need for artificial air conditioning.” (Izard, et al, 1979)

Indoor air cooling is also provided by the presence of water fountains at the patio in some houses.

Drinking water supply, use of alternative resources

The builders have adopted an exceptional urban typology, which, coupled with technical methods permitted to exploit rainwater, according to E. Passcuali, “ ... in the upper part of the medina, the houses were built on each side of the depressions of the ground caused by the rainwater runoff. These depressions facilitate the channeling of residual surface water, which initially flows to the surface before being collected by the clay pipes or still brick, and the section of which is proportional to the drained cubic.“ (Missoum, 2003) to end up in the cisterns situated in the basement of the houses.

Addition and distribution is carried out by large-scale installations, transporting water from rivers through aqueducts and underground pipelines, to storage systems (reservoirs, basins, public fountains, etc.). In addition to the rainwater harvesting tanks, public fountains regularly supplied, either by the "saqqaya" water carriers or by piped water pipes, the majority of houses have wells dug into the interior space.

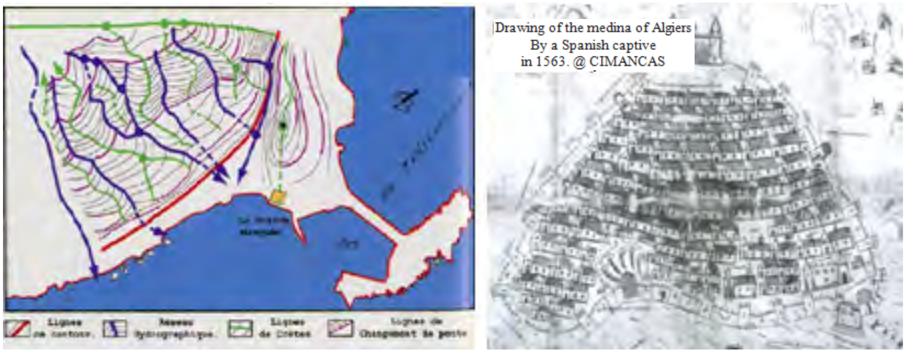

Figure 6: Perfect integration of the constructions with the topography of the site for a better exploitation of the water resources

The city's water supply obeys a set of criteria that fit directly into the sustainable development approach, namely:
Diversity of resources between the drainage of the Wadi water (Wadi M'ghasal and Wadi Knis)(Missoum, 2003), the capture of surface water, artificial water, and recovery of rainwater; Drinking water is a common good. Access is a right for the entire population; Protection of water resources from supply to distribution. Sources of water to the city are well protected (Nicolay, 1989). In order to ensure the regularity of the water supply and not to harm the water rights of others, the diversion of the water is prohibited. The right of penetration into houses for control is thus imposed on the inhabitants (Inalicik, 1986); Use of water as a mechanical energy generator. In 1551, there existed outside the medina, a river used for drinking water and runs the mills (Nicolay, 1989).

Functional organization / Environmental quality

The territory of the city of Algiers combined various functional zones necessary to ensure its autonomy, even residential, commercial, and production zones (industrial) harmoniously articulated with each other. The implantation of these three zones is the result of composition between different constraints linked to three categories of criteria, even social, environmental and economic. Each zone must satisfy a set of requirements:

The topography of the site clearly contributed to the distribution of the zones, since it makes it possible to determine a part with a high level (upper part) and another part with a low slope (lower part), articulated by the street Bab -El-Oued / Bab-Azzoun,.

The residential part must provide comfort (thermal, hygrometric, visual, sound and olfactory), security (health and urban), and privacy (ethical comfort). Indeed, this part occupies the upper part of the city with a well-hierarchized structuring, which keeps it away from nuisances.

For the commercial zone, it has to be in contact with the outside space of the city (attractiveness, accessibility and connectivity), it is therefore located on the lower part of the city facilitating the exchange with other localities and the proximity of the sea allowing Export of products to countries outside the country.

As for the industrial zone, Considered sources of nuisance, industrial activities are located outside Bab-Azzoun, with well-considered sites. The industry requiring a source of motive power for the washing of materials and the evacuation of waste water was located near streams near the sea and on the outskirts of the city to minimize the nuisances (Even the tannery in the ditch near the seashore). Those producing gaseous waste (lime kilns and pottery workshops were installed on the south-west side of the hill (better smoke evacuation by the prevailing winds of the north-west). As for the activities concentrated in the southern part of the medina, between the two walls of the southern gate Bab-Azzoun), a series of mills by the sea, and the quarry on the side of the hill. (Missoum, 2003).

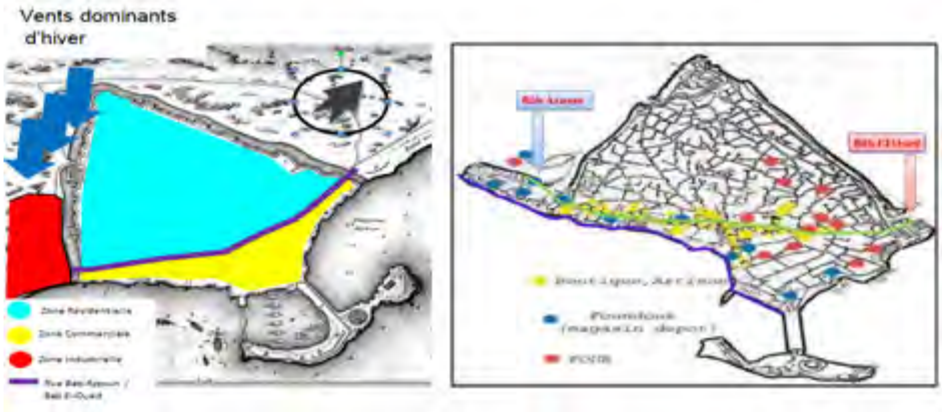

Figure 7: Spatial hierarchy of urban activities

For reasons of food security, during the Berber era, the city was equipped with cultivated areas inside its walls. These surfaces gradually disappeared with the densification of the city, especially in the Ottoman period to make way for houses as urban development progressed (Missoum, 2003).

We are witnessing a form of urban agriculture, a concept that is often referred to contemporary urbanism, which is indeed reflected in its origin at that time. The establishment of businesses in the urban area is subject to technical constraints of servitude. It is regulated by their hierarchy with the religious edifice in relation to criteria of purity. The noble and clean trades such as booksellers, perfumers, tailors are located nearby and the more the craft presents nuisances (sound and olfactory), stand far. As for artisans and traders of consumer products (bread, vegetables ...) are scattered inside the agglomeration. This functional structuring of the city reveals that the environmental concern represented the guiding thread of its urban development, following a well elaborated pattern.

Socio-spatial organization and quality of life

W.Shaler, the American consul, writes, "There is probably no city in the world where there is a more vigilant police force, where fewer legitimate crimes are committed, or where there is better security for people And properties » (Shaler, 1830)

Social values are at the origin of all the human reflection which gave shape to this city, from the urban structure, to the minute architectonic detail. They are governed by the precept "no harm, no foul", known as "la darara wa la dirar", derived from Islamic sharia. The urban and architectural structure of the city combines two contradictory concepts: to separate and to bind, to separate everything that can harm, and to combine everything that can benefit. Hence the functional separation described above in order to preserve the inhabitants from the nuisances that can be induced by public and industrial activities.
Separating foreigners for security and appropriation of space for better management, and separating men and women out of cultural and religious concerns.

The social consolidation of the urban population emerges from its organization in neighborhood units or even neighborhoods known as "houma"

"... the city and its society will evolve towards an organization recognized for the qualities of its urban management, where the neighborhoods, framed and organized, played the role of socialization and integration. " (Ichebouden, 2004)

The neighborhoods developed with subtle gradations of the character of the way. (Raymond, 1989). The road plays the role of filter whose permeability gradually shrinks by a series of interlocking spaces, going from the public space to the private space. It reflects social stratification of the population of the city.
The same logic is projected into the inner space of the introverted house, hierarchized in turn into different levels, driba-skifa-house.

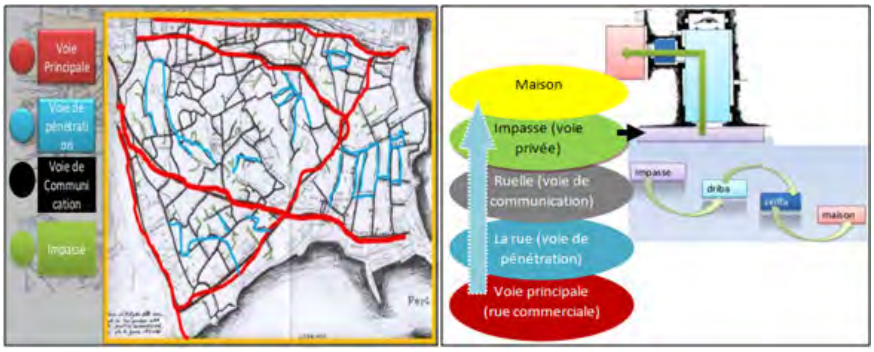

Figure: 8 Spatial hierarchy at the urban and architectural scales

Like the Muslim cities, the districts of the Casbah are the product of a fragmentation of the population into groups (units) whose members are linked according to their type, religious, ethnic or professional affinities (trades). They are constituted around a representative leader "Amin", administrator, whose authority is inversely proportional to that of the central power. (Oumlil, 1982)

The neighborhood organization gives the community autonomy of management, where the "Amin" played the role of relay between the population and the central power emanating from Istanbul (Raymond, 1985). A decentralization of power that promotes good governance.

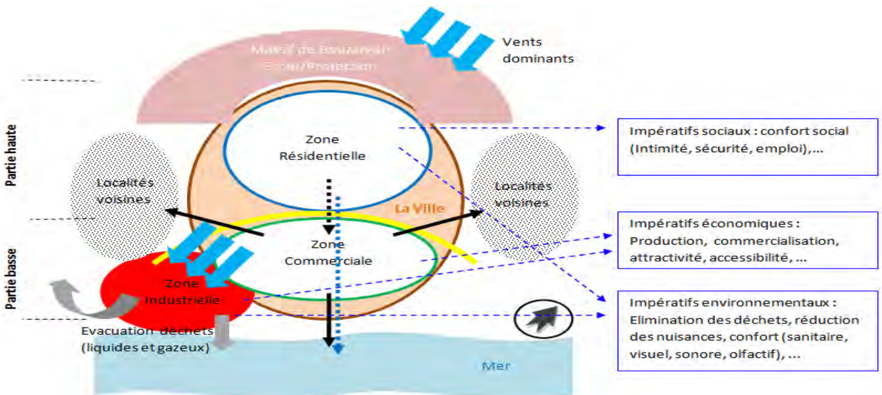

Figure 9: Urban organization as a response to social, economic and environmental imperatives

Conclusion

The medina of Algiers embodies **architecture and sustainable urbanization**, for more than three centuries, this city has not only resisted all the circumstances, but it has also kept a very high socio-economic status. Her qualities make her a timeless city. This city bears witness to a symbiotic combination of men's vital and ethnic needs with environmental factors such as site, climate and materials. It presents a sustainable habitat model implemented through ingenious responses to rudimentary resources. The medina of Algiers offers us a model of architectural and urban evolution whose feedback shows the efficiency and effectiveness for sustainable development, a system that we must seize to reconsider the codes of tomorrow.

Search limits

Given that this article deals with a historical subject and given the lack of studies that have been the subject of statistics on the contribution of the socio-urban model adopted by the Medina of Algiers to sustainable development, this research is based only on the on the historical works relating to the experience of this city during the periods of its sovereignty, even before 1830.

Today quantification cannot be done on the ground seen as the city has changed significantly, especially with the change in the social structure. However, we estimate that, despite the lack of figures, this study has enabled us to detect fairly strong indicators of the sustainability of this city.

*correspondence email: gmzmdr@gmail.com

Abstract: Achieve passive cooling in buildings is a challenge in tropical climatic regions. Therefore, a naturally ventilated courtyard could be a desirable strategy for a location with hot humid climate like Colima city in México. For this strategy to work properly, the building design composition should enhance appropriate airflow patterns to the courtyard. The *zaguán,* in traditional high mass courtyard houses, is a transitional space that serves as an entry for the house and since its regularly open it enables wind airflow between the street and the courtyard. It is worth mentioning that in this region, transitional spaces have been adapted to its environment so they can function both, as living and circulation spaces and as regulating device for other spaces in the house. For this reason, the *zaguán* could be used as a living space that can induce and control the outdoor airflow into indoor spaces. The aim of this research is to study not only the thermal performance and ventilation conditions in the zaguán as a function of its proportions, but also the influence of this transition space in the immediate spaces of the house. This study first provides a characterization of the *zaguán* in the traditional buildings of Colima including the results of a monitoring carried out in one of the case studies. Then *zaguanes* with different proportions found in the traditional houses of Colima are compared by computer simulation (CFD) with Design Builder® software in order to identify the ones that have better thermal performance and airflow rates. Finally, results are discussed among the different cases.

Keywords: Tropical courtyard, Warm humid climate, Passive cooling, Air flow, Traditional architecture

Introduction

The interest of studying traditional architecture has recently increased not only because it represents a sustainable practice, but also for their values that can be reinterpreted in contemporary architecture. As Traditional architecture is the result of years of adaptation to climate conditions of a specific place, better energy use and better living conditions may be a distinctive aspect of this type of buildings.

The present work is a presentation of an ongoing research that studies the thermal performance of the courtyard houses in a warm humid climate such as Colima, Mexico. Furthermore than characterize thermal performance of the spaces of this traditional typology, the main concern is to study on detail the performance of a specific transitional space in the house, the *zaguán.*

Traditional courtyard house

Situated among different geographic locations and moments in time, courtyard houses are a model of traditional dwelling adapted to cultures and territories. In the case of Colima, traditional courtyard houses have influence of Spanish culture combined with the local one. Its characteristics mainly correspond to a bioclimatic suitability to the environmental conditions of a place that is exposed to elevated temperatures and relative humidity (Elías López & Gómez Amador, 2015). These houses applied a series of bioclimatic strategies to minimize overheating conditions like massive adobe walls, courtyard as microclimatic space, high ceilings and transitional spaces as regulating devices.

In addition to these strategies, to prevent heat gain traditional houses have shown an adaptation that allowed a greater contact with the outside and enhance natural ventilation, a desirable technique for cooling in warm humid climates. For instance, natural ventilation can be used not only to prevent and remove heat gains in the building, but also to promote comfort in its habitants (Givoni, 1994, 1998; Auliciems & Szokolay, 1997)

Furthermore, transitional spaces may have a significant role in courtyard houses as they can regulate the exchanges with the exterior and positively influence people's perceptions of environmental comfort in architecture (Helena Coch, 2003). Additionally, in Colima they have adapted to function also as living spaces that bring a wider variety of climatic conditions into the house (Elías López, 2003).

The zaguán

The *zaguán* is a covered transitional space that serves as an entry for the house and connects the street with the courtyard (RAE, 2015). This space is a horizontal axe for the house and has two main openings, the first one, of smaller dimensions and immediate to the street, its regularly opened and the second one its protect by a gate that allows views and airflows to the courtyard. Even though this space may seem only for circulation and to control privacy but also other sort of activities have taken place there.

According to Rajapaksha et al (2002), the efficiency of a courtyard as a passive cooling strategy is related to the composition of the building in providing appropriate airflow pattern to the courtyard. In this case, horizontal axes play a significant role as they interact with the outdoor and promote air supply to courtyard while ventilating living spaces. The low-pressure zone above the courtyard, where some of the air movement is discharged, induces this wind pattern (Rajapaksha et al, 2001).

Therefore, it may be suggested that *zaguanes* have great importance because depending on its location and configuration they could drive the wind for them or through them to improve its own environmental conditions or have influence in the ventilation patterns of the house.

To determine the importance of this transitional space, the aim of this research is to study the thermal performance and ventilation conditions in the *zaguán* as a consequence of its proportions, as well as its influence in the immediate spaces of the building.

In order to characterize this architectural element on the traditional construction of Colima a random sample was carried out in the central core of the Historic City Centre. *Zaguanes* of twenty-seven traditional houses were registered to establish their representative and variable characteristics that could influence airflows and thermal performance. Characteristics such as disposition inside the house, orientation of the façade, openings areas and ratio between them, construction materials and proportions were taken into consideration as important design parameters. From all of them, proportion was chosen to be the main variable and object of this research.

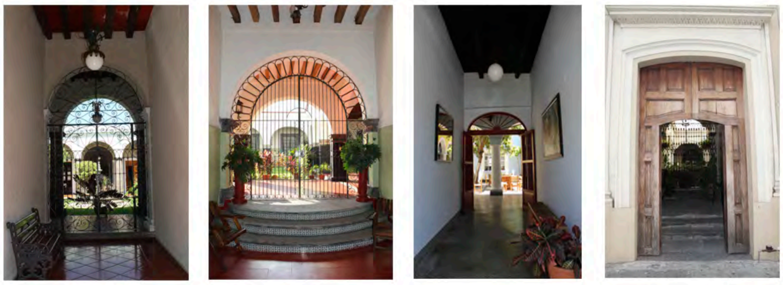

Figure 1. *Zaguanes* from traditional courtyard houses of Colima, México.

Ambient climate

The buildings investigated in this study are in the downtown of Colima, Mexico, at 14’ 37’’ N latitude and about 500 m above sea level. Elevated temperatures and relatively high levels of humidity define the ambient climate. The annual mean temperature is 25 °C. While the month with lower temperatures is January with a mean temperature of 23°C, the months with higher temperatures are May, June and July with means of 27°C. For this work/study, the month of May present the critical conditions with higher temperatures of 35°C and minimum temperatures of 19°C

Field investigation

A case study of a representative courtyard traditional house of Colima was selected to make a field investigation. The 560-square meter rectangular building form is a single storey dwelling that has an almost central rectangular courtyard measuring 9.4 and 10.45 m. Some of the characteristics of this dwelling are a façade oriented to Southwest, a *zaguán* with proportions of 2m width, 6.4m long and 3.88m height. The ratio between its openings areas is 1.24, with the smaller area of the opening immediate to the street (3.6 m^2). The construction systems consist of high mass adobe walls and ceramic roofs.

Data collection

The courtyard building was monitored for 7 days from 12 May to 19 May 2016 where *zaguán* remained opened from 9:00 to 20:00 hours. Air temperature and radiant temperature measurements were taken at 1-hour intervals using datalogger sensors, which recorded day and night. Also, meteorological conditions were recorded each hour at a weather station built on the site using temperature and humidity sensors.

Additionally, wind velocities were recorded along the longitudinal axis of the *zaguán* in one of the days during three periods of 25 minutes at 8:00, 14:00 and 19:00 hrs. Measurements were taken at 1-second interval making a total of 1500 samples which were averaged for a further analysis.

Instrumentation

For air temperature measurements, we use datalogger U12-012 sensors. The accuracy was stated as ± 0.35°C from 0–50°C. Instead of radiant temperature, black globe temperature was measured using a black sphere of .10m on an H08-004-02 Datalogger. The accuracy of this instrument is ± 0.4°C from a range of -20° to 70°C.

For indoor air velocity measurements, we use omnidirectional hot-wire anemometers with dataloggers Delta Ohm model HD2103.2. These have a measuring range from 0.0 to 40 m/s and accuracy of ± 0.2 %.

Measurement locations

Temperature measurements were recorded in the courtyard and in selected indoor and transitional spaces of the building (refer Fig.2). Indoor spaces were measured for air temperature and black globe temperature at their volumetric centre. Wind velocity measurements were recorded at 1.1 m heights at each space along a longitudinal axis that went from the street to the courtyard and going by the *zaguán* the location of the sensors can be appreciated in Fig. 2. As for, outside weather conditions sensors were installed on the site at a 3 m level from the rooftop house ensuring freeness from wind and solar obstructions.

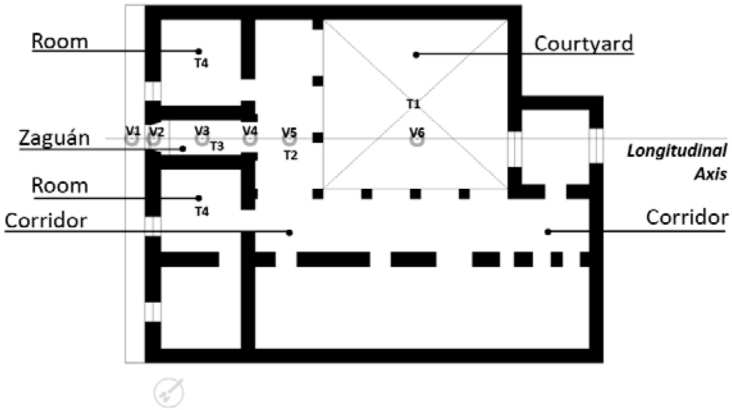

Figure 2. Courtyard house used as case study and measurement locations.

Results of thermal and ventilation measurements

The assessment of measurements is mainly concerned with comparing the *zaguán* thermal performance and wind velocities with other spaces of the house. Regarding dry bulb temperature measurements, the rooms had the lowest temperature swing compared with the exterior temperature. The interior maximum temperature of the rooms was 6 K less than the exterior maximum temperature, with a thermal delay between 3 and 4 hours. The *zaguán* interior maximum temperature was 2.3 K less than the outdoors maximum temperature. And by comparing the corridor and the "zaguán", both transitional spaces, similar thermal performances were observed. Nevertheless, the zaguán had lower temperatures by 0.34 K when the higher temperatures were presented outdoors. The temperature profiles along the day can be appreciated in Figure 3.

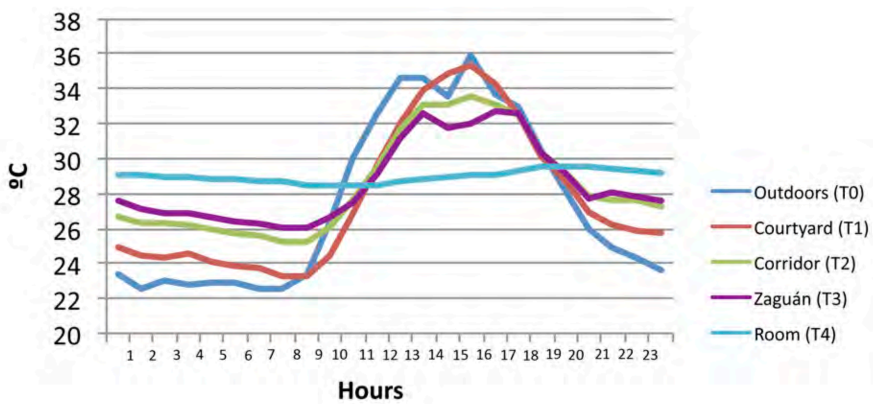

Figure 3. Dry bulb temperatures comparison between different spaces of the house in a representative day

As for wind velocity, the average wind speeds measured on the longitudinal axis were compared. The results show higher wind speeds in the street (V1) than in the courtyard (V6) and in most cases the higher wind speeds were recorded during the period of 14:00 hrs. Among the measurement points inside the dwelling, the opening near the street (V2) had the highest wind velocities. Followed by the points located in the corridor (V5) and in the opening near this one (V4), where there was a slight increase of the speeds in comparison with the centre of the *zaguán* (V3) (refer Table 1). In addition, the wind direction from the street to the courtyard was identified as prevailing.

Table 1. Wind velocities in three periods of time.

		Street (V1)	Opening (V2)	Zaguán (V3)	Opening (V4)	Corridor (V5)	Courtyard (V6)
8.00.00	MAX	3.54	1.85	1.29	1.23	1.36	0.89
	MIN	0.15	0	0	0.02	0	0.01
	MEAN	1.01	0.35	0.29	0.35	0.30	0.22
14.00.00	MAX	7.05	5.62	3.42	3.28	3.7	1.49
	MIN	0.08	0.04	0.07	0.06	0.06	0.06
	MEAN	1.57	1.52	0.92	0.94	1.04	0.41
19.00.00	MAX	5.64	3.61	2.97	2.44	2.49	1.43
	MIN	0.19	0.06	0.05	0.06	0.03	0.05
	MEAN	1.81	0.92	0.61	0.72	0.60	0.40

The field investigation of the case study showed the importance of the building fabric to prevent solar heat gain and that the use ventilation as a strategy to remove heat gain may only be applied between 19:00 – 8:00 hrs., when the exterior temperature its lower than inside one. On the other hand, in these houses transitional spaces bring different thermal and ventilation conditions so that the inhabitants could use them as living spaces depending on the daytime and season. For example, in the *zaguán* “zaguán” an average air velocity of .92 m/s was recorded during 14:00 hrs. that could extend the upper limits of comfort dry bulb temperatures by 3.49°C under temperatures of 32°C in warm humid weather conditions (Auliciems & Szokolay, 2007).

Proportion comparison

In order to perform the thermal evaluation of the *zaguán* with different proportions under the same conditions, Energy Plus simulation program and Design Builder® as an interface were used to get graphic and numerical results approximated to reality. The simulation parameters were obtained from the previous characterization and meteorological-data from the nearest weather station of National Water Commission (CONAGUA) for the month of May 2016.

Results

To evaluate and validate the simulation program as an acceptable tool a previous simulation was carried out using the measurements of the representative case study house. When comparing the simulation results and the field measurements a significant correlation was found. The dry bulb temperatures average in the *zaguán* in both cases showed a difference between them of 0.22 K.

In addition the CFD (computational fluid dynamics) simulation for the wind velocity was carried out. As it can be appreciated in Figure 4, the air velocity flows from the *zaguán* to the corridor, at the outlet of the corridor, the velocity profile shows a parabolic shape, this is due to the friction of the fluid flow with the walls of the zaguán. In certain conditions, this behaviour represents the fully developed flow of the fluid along the zaguán.

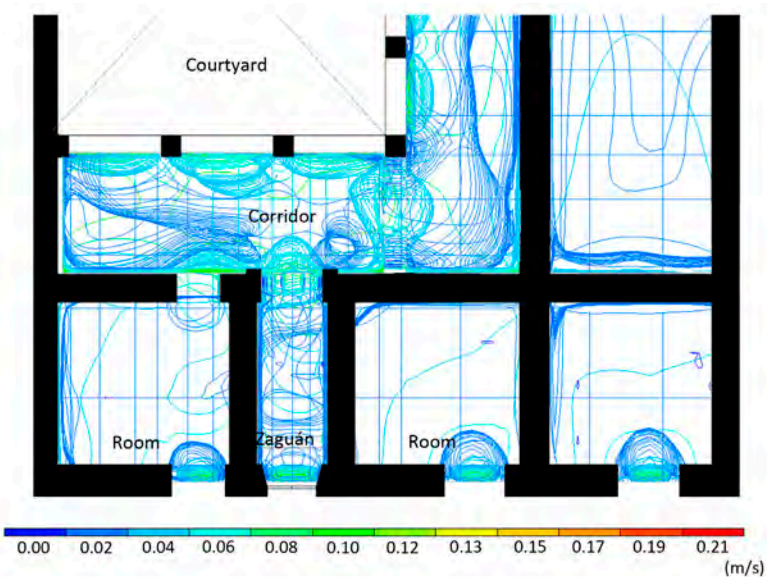

Figure 4. Velocity profiles. CFD simulation results in representative courtyard house.

Analysis unit

Once the simulation program was validated an analysis unit was proposed to make the variations concerning the *zaguán* proportions. The purpose of this analysis unit was to make a simplification of a traditional courtyard house so that it would facilitate the analysis and allow greater control of the variables. The component spaces of this unit were the *zaguán*, the immediate corridor and rooms, as well as the courtyard. All of them spaces that we were interested in studying. To establish he analysis unit characteristics, the previous data of the *zaguán* random sample and the characterization data of the representative house were taken into consideration. This in addition to information of previous investigations of traditional courtyard houses of Colima City that have been carried out.

The proposed analysis unit was a 243-square meter rectangular building with a rectangular courtyard measuring an area of 91 square meters. The building façade was oriented to Southwest, the proportions of the *zaguán* "zaguán" were 2.6m width, 5.9m long and 4.55m height. These proportions are the result of the mean range of values obtained from the random sampling. Also, on both sides of the building adiabatic blocks were placed to avoid heat losses or gains (refer Fig.5).

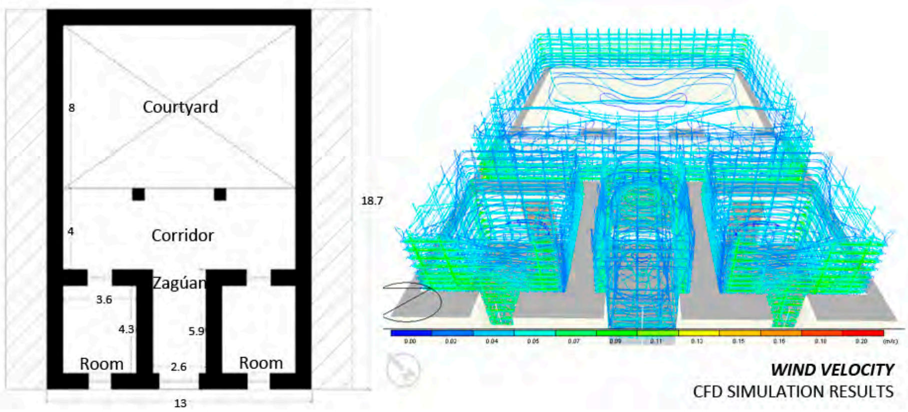

Figure 5. Analysis unit floor plan and results from the CFD simulation

Height comparison

The heights registered in the zaguán of the Colima´s traditional houses went from 3.8m to 5.3m. The lowest dimension (Case 1), the highest dimension (Case 3) and the dimension of the unit analysis (Case 2) were used to model the three cases to compare. In this comparison, every other parameter except from the building height that conditions the zaguán height remains constant.

The assessment of measurements in this stage is mainly concerned with the effectiveness of the zaguán proportions in lowering the air temperatures of its own and surrounding indoor spaces below the level of daytime ambient temperature. As well as to achieve maximum air flow and wind velocities.

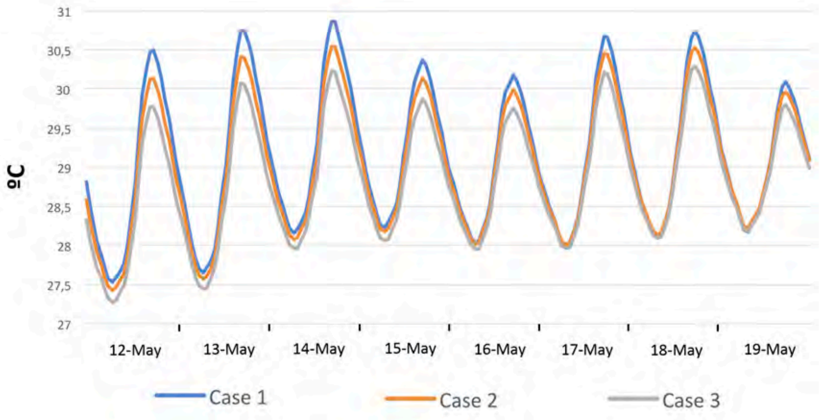

Figure 6. Dry bulb temperature comparison between the three different cases of height.

The simulations carried out for the period of the 12 to 19 of May 2016, showed a difference of 0.57 K in the maximum air day temperature of the *zaguán* between the cases of lower and higher dimensions' height. Case 1 that was the one with lower height presented the higher temperatures. Moreover, the radiant temperature of the *zaguán* with higher dimensions was 0.79 K less than the case with lower dimensions (refer Fig.6).

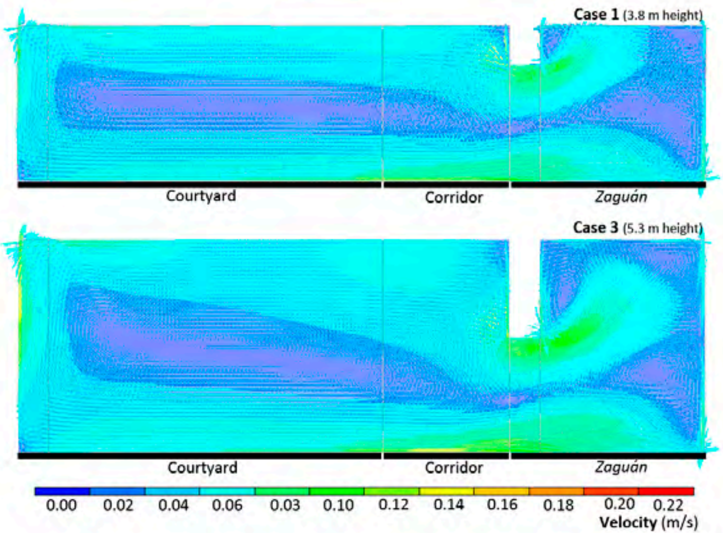

Figure 7. CFD Results. Comparison of velocity vectors between cases of lower and higher height dimension cases with the annual average speeds. Longitudinal slide.

Temperatures of the three models were very closed but by comparing wind velocities results in the *zaguán* greater differences were observed. For example, case 1 (3.8m height) showed an average wind speed of 0.60 m/s and a maximum of 2.08 m/s. Case 2 (4.55 m height) showed an average wind speed of 0.67 m/s and a maximum of 4.44 m/s. Finally, Case 3 (5.33 m height) showed an average wind speed of 0.75 m/s and a maximum of 5.8 m/s (refer Fig. 7).

Comparing the air temperatures in the immediate rooms, the simulation for the zaguán, showed a difference of 0.54 K in the maximum air temperature of the day between the cases of lower and higher dimensions' height. Case 1 that was the one with lower height presented the higher temperature.

Conclusions

Until now only the heights have been compared and these partial results suggest that the changes in the proportions concerning height may not have a major influence on the air temperature of this space. However, greater differences on wind speeds have been observed by modifying the proportions. This brings up the question of whether the *zaguán* may have a greater influence by extending the upper limits of comfort in the inhabitants by increasing wind speeds.

The simulations on this research were realized as if the *zaguán* remain opened during day and night. Which leads us to think that different results may have been obtained if this space remained opened when the exterior temperatures were lower and closed when these were higher. This possibility of control the openings emphasize the importance of *zaguán* as a space in which inhabitants could interact and modify their environment.

Although further simulations and analysis may be need to evaluate the effect of the proportions of this space on the thermal performance and ventilation, we can assume that the importance of this space as a result of its unique conditions. It is reasonable to think that if this element of architecture that have transcended through time, adapted to specific climate conditions and remained in use is a consequence of its important value. Therefore, it may deserve a detailed and deep study that allows us to reuse them according to the characteristics and way of life of the present.

Design to Thrive

Floating Houses: A design for flood resilience innovations in Bangladesh

Shimantika Bhattacharjee[1], Nandan Mukherjee[2]

[1] Division of Industrialized and Sustainable Construction, Luleå University of Technology, Luleå, Sweden, shimantika.bhattacharjee@ltu.se

[2]Centre for Environmental Change and Human Resilience (CECHR), University of Dundee, Dundee, UK, n.mukherjee@dundee.ac.uk

Abstract: People living in the coastal regions of Bangladesh suffer extremely due to floods. Every year 20% of the land mass (~27,000 km^2) and 30 million inhabitants are exposed to flooding that triggers casualties, infrastructural damage, and deprived access to basic needs. Many policies and strategies already exist for managing flood-related disasters. Flood-shelters save lives but rarely equipped with sufficient food, clean water, sanitation, and electricity. New strategies are required to provide resilience in flood prone areas. This conceptual paper presents an innovative and integrated approach for up-scaling and enhancement of resilience in the flood prone regions of Bangladesh. The paper shows a conceptual design for a floating house with six innovation techniques for self-sufficiency and durability. The techniques include wind and flood tolerant structure, vertical gardening, rainwater harvesting, poultry and bio-digester unit, cage fishing, and renewable energy implementation. The techniques are low-tech and cost-efficient. Use of locally available materials enhances the resilience before and after flood. The design presents equality, balance and immense opportunities for the inhabitants. The 3R strategy (reduce, reuse and recycle) is one of the fundamental concepts of this floating house design. The design explores the possibilities of food security, waste management and energy challenge.

Keywords: Flood, resilience, up-scaling, environmental, water

Introduction

Hydrological occurrence like flood is a common phenomenon in Bangladesh as it is situated on the Ganges Delta and having distributaries that flows into the Bay of Bengal (Islam et al., 2010). The country is affected by flood almost every year and causing damage to people's lives, crops, infrastructure and economy. One of the prominent reason behind such hazards is abrupt changes in climate that contributes in sea level rising and therefore results in flood occurrences (Mimura, 2013). Numerous initiatives were taken into consideration to manage flood related disasters in Bangladesh which includes structural engineering projects such as embankments, raised platform and other temporary shelters (e.g. National Water Policy, National Strategy for Disaster Management, Bangladesh Climate Change Strategy and Action Plan). As a matter of fact this initiatives often results in water logging and restrict sediment flow, reducing agricultural productivity and also generates social vulnerability. The objectives of such projects are deprived of a systematic and integrated approach and are not optimized for long term considerations. The systematic and complex nature of resilience and the interdependence between environmental hazards and social, economic and welfare need of people is often ignored while managing the flood related disasters. This lead to a devastated effect on people's life during pre and post phase of flood.

Climate change is enhancing intensity, frequency of floods which then exacerbate many other challenges, including livelihoods, poverty and gender relations in interrelated ways (Tanner, et al., 2007). The interrelated ways of flood impact is elaborated in Table 1.

Table 1: Integrated nature of flood impacts in Bangladesh

Flood Impact	**Explanation**
Loss of livelihood	People cannot continue income generation activities (e.g. agricultural production, labor) during/after floods. Coping involves relying on micro-credit & emergency aid which increases debt and poverty.
Poor health and mortality	Mortality from flood occurs from drowning, snake bites, and malnutrition. Poor health delays recovery and death can result in family members falling into extreme poverty.
Deprived access to water and sanitation	Permanent water supply and sanitation points become inundated. The temporary source of potable water is insufficient and of inadequate quality. Open defecation and poor waste management can pollute water. Restoration of water supplies and sanitation points is expensive, increasing the burden both on the households & public entities.
Food and nutrition	Food and nutrition security during and after floods is affected through loss of agricultural production and livelihoods and high reliance on emergency support/aid. Food insecurity causes mortality or ill health, limiting recovery.
Lack of safe places during floods	Temporary migration to flood shelters is key for poor households. However, shelters do not accommodate most people. Children and women can experience abuse and rape. This, combined with limited essential support services during floods (partly because of theft of supplies) affects willingness to use shelters.
Loss of education	Loss of school days is common (e.g. when schools are used as shelters or when they cannot access schools). It can lead to permanent dropout.
Damage to infrastructure	Restoring transportation, communication, & other infrastructures increases the nation's economic burden and limits spending on other crucial needs (e.g. health, poverty alleviation, water supply, sanitation).

Therefore, the study creates an urge to take a sustainable, integrated and longer-term approach that simultaneously enhances generalized resilience (e.g. livelihood and poverty related challenges) while also enhancing resilience specific to flooding. This study emphasizes on developing a conceptual model of designing a floating house integrating six innovation techniques for flood prone areas in Bangladesh. It conceptualizes the idea of floating houses functioning both on land and water. Similar examples on amphibious houses were found in Europe and in the USA situated in two different climate zones (English, 2009). Another study showed a similar design consideration for the urban poor during the crisis of flood (Prosun, 2011) . Moreover, implementation of flood resilient house practices and inclusion of the new guidelines for buildings situated in the flood prone areas in Bangladesh is necessary.

Figure 1 shows the inundated areas during flood events in 1974, 1988 and 1998. It can be seen that the percentage of total area inundated was approximately 35% in 1974, which increased to around 49% by 1998.

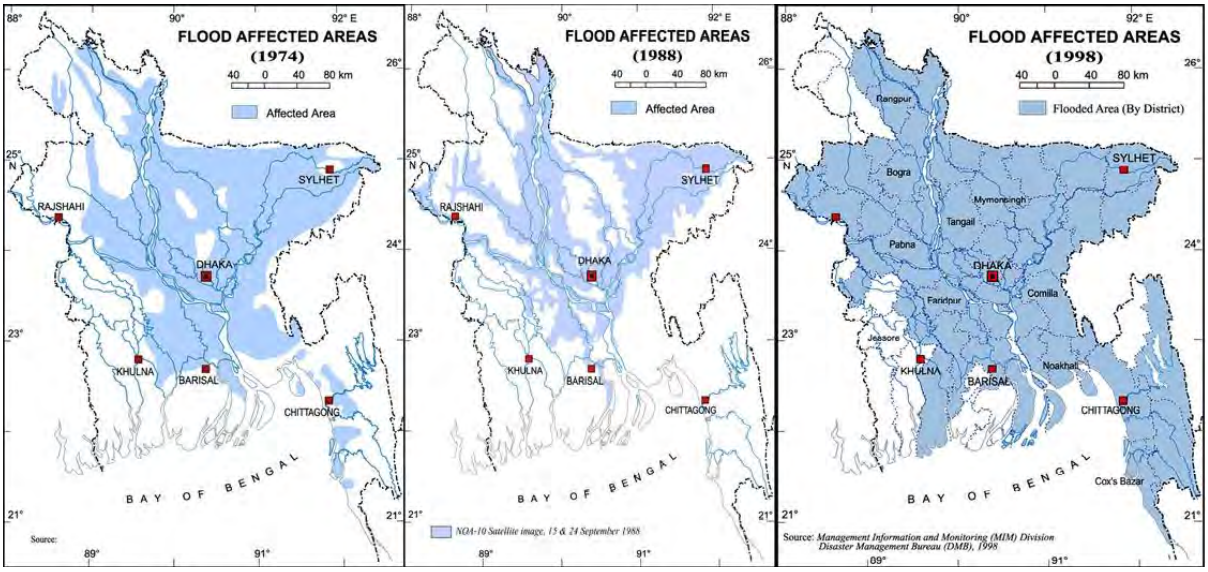

Figure 1. Flood affected areas in the map of Bangladesh (Agrawala et al., 2003)

Aims and Objectives

The aim of this study is to develop an innovative and sustainable floating house design which is environment friendly and can be built using locally available materials. The concept is to design a house to cope with flood and corresponding water related disasters. The floating house is conceptualized on “passive house techniques” that can be adapted and optimized towards local climate condition. The above context provides necessary ground for a permanent static elevation in the form of residential structures to avoid forced displacement of human population during flood. The target is to evaluate energy-efficient innovation strategies to enhance the resilience of households and communities to before, during and after flooding. Specific objectives are given below:

1. Mitigation of climate change induced loss and damage.
2. Implementation of reduce, reuse and recyclable potential in the floating house design.
3. Self-economic hub for livelihood support and income generation through food production.
4. Exploration of critical resilience dimensions and ensure safety and security of the flood affected people.
5. Replacement of non-renewable sources by renewable sources for energy production.
6. Energy-efficient design aspects and passive strategies to reduce the environmental burden and GHG emission.

Approach and methods

A conceptual floating house model

The goal of this study is to test the floating house concept in a real environment. Therefore, monsoon flood-prone areas of Southern Bangladesh were selected. The locations are Char Bhaga, Sakhipur, and Tarabunia in the Bhedarganj upazilla at the Shariatpur District. The locations were chosen based on the following considerations: (a) are highly exposed to monsoonal flooding; (b) are readily accessible; (c) face complex issues relating to vulnerability.

The idea of a floating house has been conceptualized to address the climate change issues. The design is a self-sufficient floating house which emerge as a source of basic needs during the crisis period as shown in Figure 2. The idea of a “floating house” is formulated based on the concept of a tree. The physiological and psychological attributes of a tree has been considered thoroughly while conceptualizing the idea of a floating house. It is considered to be a self-sufficient house with the ability to producing food through vertical vegetation even in the period of flood. This floating house can serve as a potential shelter for the victims of flood prioritized to improve their condition through safety, security and income generated activities.

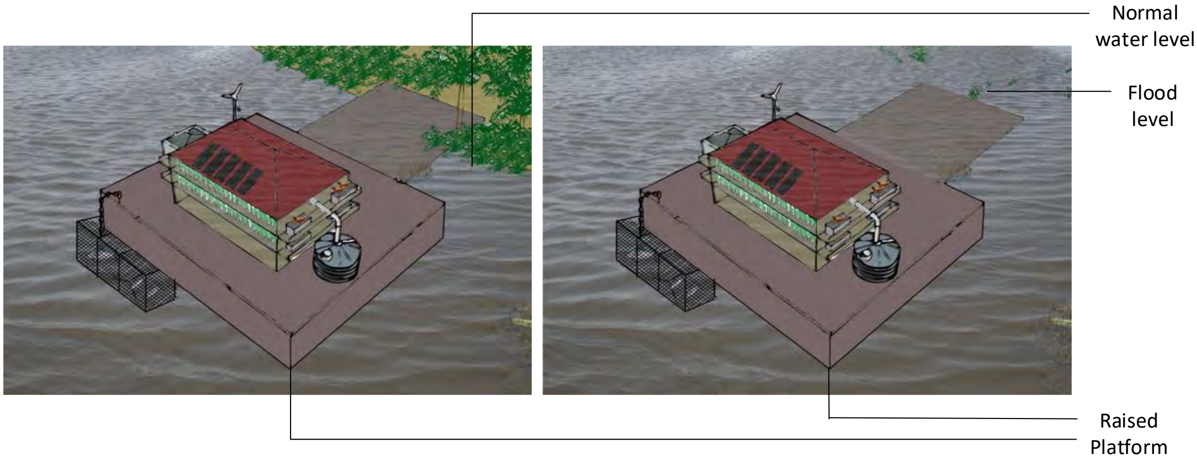

Figure 2. The conceptual 3D floating house model before and during flood

The project is highly innovative for three reasons. First, the idea of a floating resilient house that integrates multiple other innovations (Figure 2, Table 2) to provide renewable energy; income generation; food production before, during and after floods; and security is entirely new. Second, a participatory approach can be included so that it can it provide learning methods and developmental evaluation to encourage innovation of community members in the project. Third, the design of the up-scaling strategy is also highly innovative in the way it draws on extensive local insights gained through collaborative learning approaches that will help understand both the effectiveness of the resilience innovations and of the participatory process used to develop and implement them.

The study will also add significant new knowledge about resilience, including about: (1) the systemic nature of resilience, including relationship between diverse challenges facing local people; (2) integrated approaches and innovations to enhance resilience; (3) designing upscaling strategies for resilience; and (4) new ‘know how’ knowledge about implementing resilience through inclusive and participatory approaches, including the challenges and opportunities of doing so.

Innovation in the floating house concept

The aim of this floating house is to with-stand the current and future climate change impact and simultaneously contribute to reduction in GHG emission through environment friendly technological interventions. Due to the adverse impact of climate change it is therefore evident to build houses sustainably. Passive strategies such as implementation of renewable technology have been introduced to address the climate change issues. A few innovation techniques have been integrated with the floating house concept which is described below precisely (Nayar, et al., 1989) (Brugere, et al., 2001) in Table 2.

Table 2: Specific innovations to be integrated into flood resilient houses

Innovation	Explanation	Evidence for applicability
Wind tolerant floating houses	A floating house built using local materials to be resilient to floods and wind. This addresses problems of temporary displacement to shelter, inadequate space, abuse and assault of children	There has been demonstration regarding Cyclone Proof Houses in Bangladesh designed by architecture dept. of Brac university. House Building Research Institute in Bnagladesh also developed a floating house built with locally available materials (Ferro Cement Floating House (https://goo.gl/Sm7rWJ). Engineers at the University of Alabama, Birmingham are using similar concepts (https://goo.gl/NYX26T) and the Asian Disaster Preparedness
Vertical gardening/ hydroponics	Walls pf floating houses for vertical gardening using hydroponics to enhance food security and income.	Accommodating agriculture as economic activity in a limited space and during the time of emergency is critical. Extensive research has shown that hydroponically grown crops yield 20% more produce than conventional farming techniques.
Rainwater harvesting	Underground and overhead tanks to store rainwater provide safe water supplies	Rainwater is the safest drinking water option during the flood and the potential for rainwater harvesting is widely researched. BRAC and NGO forum have implemented such options in Bangladesh (https://goo.gl/xk8fRj)
Poultry and Biodigester unit	Biodigesters produce power from household & poultry waste, with residue used as fish feed & fertilizer.	The feasibility of bio-digesters has been widely tested in Bangladesh. IDCOL, a Government-supported NGO in Bangladesh has already implemented thousands of such low-cost demonstrations in Bangladesh (https://goo.gl/EfODgG).
Cage fishing	A fishing unit using aquaponics provides protein and income.	This complements vertical agriculture and has been researched extensively (e.g. Brouwer et al, 2007) and implemented in the 'Fisheries Projects' in Bangladesh (https://goo.gl/MxtLeU)
Renewable energy	Small hybrid solar panels/ wind turbines will generate electricity to supplement the biodigester.	The applicability such work has been demonstrated since the 1980's (e.g. Nayar et al,1989). NGOs in Bangladesh, including BRAC, Grameen Bank, IDCOL has already implemented millions of such systems (https://goo.gl/Px2YSa).

The figure below (Figure 3) shows the floating house model integrated with the six innovation techniques summarized in Table 2.

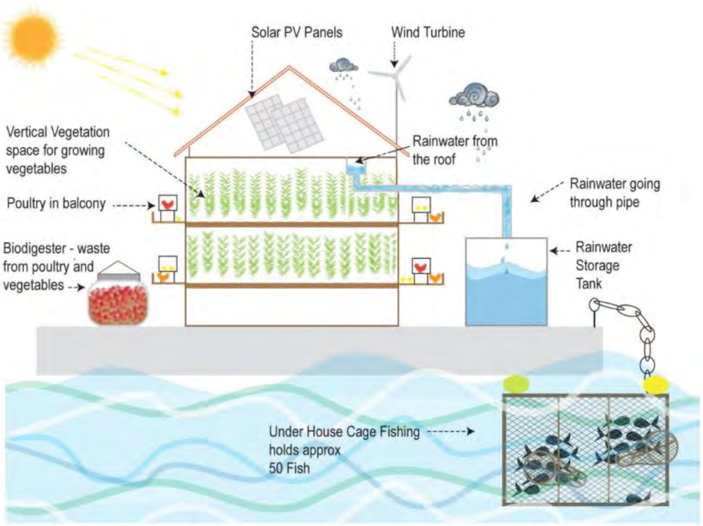

Figure 3. A conceptual diagram illustrating the floating house model integrated with six innovation techniques

According to the concept of amphibious structure the floating house will be designed in such a way that it can elevate upwards during flood and as the water level recedes it will return to the ground level. The water level scenario during pre and post flood condition is shown in figure 4.

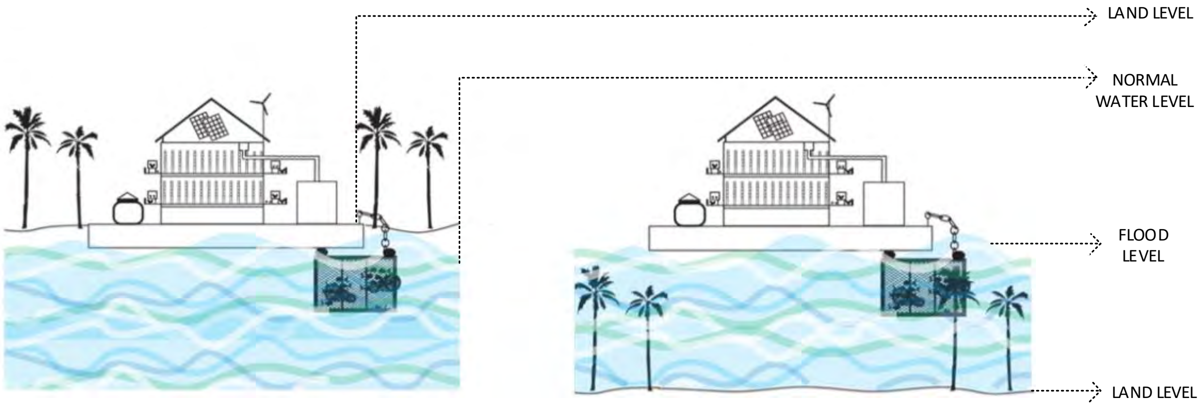

Figure 4. Water level scenario before and during flood

Addressing Objective 1: Mitigation of climate change induced loss and damage

Climate change is an unavoidable environmental phenomenon that induces loss and damage in different dimensions (Pinninti, 2014). There are certain types of efforts for managing loss & damage which has long term environmental or social consequences. Building embankments along the river side to reduce the exposure of the affected population, however, can obstruct the sedimentation in the flood plain which might result in irrecoverable loss to the floodplain dependent ecosystem components and services (Potter, 2013). Simultaneously there are certain conditions or limits to the perceived adaptation and mitigation efforts where nothing could be done, or possible in future. For example, the current level of greenhouse gas concentrations in the atmosphere would let us such situations where some level of warming is certain, no matter how robust is our emission reduction targets or adaptation efforts will be. The floating house concept is an effort and approach towards tackling the water related hazards like flood in a sustainable way and thus contributing towards reducing the greenhouse emissions through different innovation techniques. The longer term goals are: a) r*eduction towards the exposure of water related hazards, b) minimum level of residual impact on the environment, and c) maximizing the potential for complementary or double benefits from adaptation and mitigation.*

Addressing objective 2: Implementation of reduce, reuse and recyclable potential in the floating house design.

The 3R strategy is a sustainable way of managing the waste and the resource value of materials can be fully utilized in the process. The rain water harvesting determines the reuse potential and as can been from figure 3 rain water will be collected in the storage tank and filtered through environment friendly bio-sand filtration. Later this water can be used daily for household and during the emergency situation like flood. It does not only produce gas but also produce fertilizer from the organic household waste and poultry. Gas can be used for household cooking and the fertilizer can be provided as the food for plants and fish. Therefore, the organic wastes are being reused and recycled in the process. The 3R strategy decreases the amount to be disposed and thus contributes to reduction in greenhouse gas emission. The process is low-tech, sustainable and cost-efficient and therefore people can be benefited from adopting such innovation technique.

Addressing objective 3: Self-economic hub for livelihood support and income generation through food production.

The floating house concept has been developed to improve the wellbeing of the inhabitants. As already mentioned that hazards like flood has a disastrous and detrimental impact on economical, physical and psychological condition of the affected people. Supporting the livelihood were prioritized during the formulation of the concept. The house is a source of self-economic hub. Food security can be ensured through production of vertical vegetation, poultry and fish (see figure 3). Moreover, the surplus vegetables, fish and poultry can be sold in the local market and thus serve as a purpose of income generation activity for the inhabitants.

Addressing objective 4: Exploration of critical resilience dimensions and ensure safety and security of the flood affected people

The temporary shelter often fails to provide the basic facilities and services to the affected people. Report shows that such temporary shelter cannot provide proper safety and security towards women and children (Brouwer, et al., 2007). Therefore, instead of a temporary shelter a permanent solution like floating house can alleviate their pains and sorrows.

Addressing objective 5: Replacement of non –renewable sources by renewable sources for energy production

Bangladesh is fully dependent on fossil fuels to generate electricity which are being depleted at an alarming rate. People suffer from electricity shortage extremely which is considered as one of the biggest crisis at present. However, approximately 30% of the total populations are connected to the national electricity grid of Bangladesh (Taheruzzaman et al., 2016). People living in the village areas has access to the rural electrification grid which has very poor performance and frequently suffers from shutting down of electricity. The country has immense opportunities for implementing solar energy (Islam et al., 2014). As being situated in semi–tropical region of south Asia, Bangladesh receives abundant sunlight year round. Scientists with support from local NGO's, rural electrification board and the infrastructure development company have initiated the solar panel implantation plan in the rural areas of Bangladesh (Ahammed &Taufiq, 2008). Using daylight the solar panels installed on the roof can produce electricity and meet the needs of local people (Prasad & Snow, 2014). Apart from solar panels the use of wind turbines have also been considered to generate electricity when there is no sunlight available (Nayar, et al., 1989). The extra electricity produced can be sold to the local electrification board as well. Successful implementation of these passive energy sources can encourage other rural areas to adopt this technology and thus contribute in reducing the environmental burden.

Addressing objective 6: Energy-efficient design aspects and passive strategies to reduce the environmental burden and GHG emission

The floating house is naturally ventilated. It is considered as one of the main techniques for keeping moderate temperatures in buildings specially situated in the hot dry and tropical climates. The natural ventilation can help to improve the indoor air quality through fresh air flow. Integrating the vertical vegetation is another strategy incorporated in this concept to improve the indoor and outdoor environment. Addition of vegetation on the facades will generate lower temperature during warm summer months comparatively than the conventional façades. Both of the above mentioned strategies can reduce the energy consumption and greenhouse gas emission simultaneously.

Conclusion

The approach and collaborative nature of this concept are highly amenable to scaling up and longer term sustainability that would reach around 20,000 households and 1 million people. This concept describes an innovative approach towards adaptation compared to the traditional flood resilient infrastructure. The resilience initiatives have been chosen because of their direct relevance to local needs, affordability, and ability to address multiple challenges facing households. The study also specifically seeks to enhance potential scalability through learning about the effectiveness of innovations, how they can be implemented and by designing scaling approaches. It also includes approaches to implementation that are community led rather than imposed by engineers, planners or researchers. Overall, the combination of attention to appropriate innovations, the process of engagement and inclusivity, designing scalability, and consideration of wider governance and policy issues greatly enhance the potential for sustainability and wider impact.

Abstract: In Brazil, the public sector is the largest constructor in the country. However, considerations of the impacts of the conventional constructive techniques adopted and green technologies alternatives hardly take place in the public sector. Audit works carried out by the Federal Government's high internal control body cover public projects and works but for compliance measurements mostly. In addition, these audit works help to improve public policies. Thus, this study is aimed at include environmental sustainability assessment as a subject part of public audit works regarding to urbanization. This research used the case study strategy in a descriptive way in order to apply an analysis model. It lays on a specific thematic clipping: integrated water management under the environmental layer view. The constructed analytical model is based on sustainability indicators. The selected urban fraction is a marginalized area, in an insular city. Public power is carrying out urbanization works in this locality. This research shows the viability to include principles of sustainability assessment in audits works of urbanization. Analyzing the suitability using such principles in public works could enforce best management practices to become an alternative or a complementary part to the conventional public network.

Keywords: Sustainable Urban Planning, Integrated Water Management, Public Works Audit, Sustainability Indicators, Clandestine Human Settlements.

Introduction

The Brazilian government is gradually seeking modernization. Institutions are trying to conform to the principles of good governance and have been adopting instruments of performance analysis and accountability more frequently (Ministério do Planejamento, 2009). Analysis models, indicators and indexes have been developed in the last decades to become management and result evaluation tools (Ministério do Planejamento, 2009). Similarly, control bodies have been incorporating such tools into auditing works on governance, public policies and government expenditure assessments. Such issues must be monitored to guarantee they conform to both the needs of the State and of the community. In addition, the right to a balanced environment is one of the fundamental needs of the Brazilian citizen (Brazil, 1988). The need to use indicators of environmental sustainability arises within this context. An indicator can assess the estate or point in time of a project regarding a specific goal and contribute to the elaboration of plans for improvements (Sustainable Measures, 1999, in Sattler, 2015).

The Brazilian legislation establishes that goods and services acquired by the public authorities must promote sustainable development (Brazil, 1993). It also requires that public works projects should be technically feasible and have adequate environmental treatment. Despite the national legislation requirements, there has been little progress towards achieving sustainable public works (Lima, 2013). The Brazilian government is concerned to provide basic sanitation but the efforts to use more environmentally sustainable solutions are incipient. In Brazil, the Office of the Comptroller General (CGU henceforth) is the Federal Government's high internal control body responsible for conducting public works audits. However, little is discussed about ecological solutions to basic sanitation. Public works audits commonly refer to the conformity with the bidding process, documentary compliance and compatibility between design and implementation in physical, chronological and financial terms.

This study aimed at proposing an auditing method for urbanization works using environmental sustainability indicators and Best Management Practices (Ellis, 2010; Niemczynowicz, 1999) to achieve integrated water management (IWM) techniques. The goal of this study also was to support that, with the aid of environmental indicators (i.e. sustainable urban drainage systems, low-impact urban design and development, water-sensitive urban design, green infrastructure), audit reports can be a tool to enforce a governance leap in the formulation of public policies for the execution of urban works.

Research Method

The case study was selected from a poor community on a hill, called Maciço do Morro da Cruz (MMC henceforth), which is located downtown Florianopolis, a coastal and insular Brazilian city in Santa Catarina State, south of Brazil. Florianopolis has the third highest Municipal Human Development Index (IDHM: 0.847; UNDP, 2010) and one of the highest per capita incomes of Brazil. As such, there are excellent housing options for the portion of citizens who can afford it. However, there are places in the city occupied by poor clandestine land settlements in precarious conditions. These segregated areas are one of the several problems related to accelerated population growth in Florianopolis, which in the last 30 years, has been the result of public policies without proper development strategies and urban planning (Sugai 2015). Currently, there are 18 irregular settlements in MMC, which is a 283-meter-high granite hill (Tomás, 2012; Hübner *et al*., 2004). The local government legally recognized the need to provide urban services to the MMC's inhabitants to reduce social inequality in these precarious settlements (Governo do Estado de Santa Catarina, 2012; Salomé, 2014). Efforts to consolidate this plan have intensified since 2007 (Tomás, 2012; Ministério do Planejamento, 2016), with CGU supervising the urbanization works since 2012 (CGU 2014; CGU, 2016).

The study site selected for this research was a street called Nova Descoberta within Mont Serrat Community, one of the 18 tenements in MMC (Figure 01). Nova Descoberta Street is located in an environmentally vulnerable area, designated as a Limited Use Preservation Area[1] (or APL in Portuguese acronym) by the Brazilian Forest Code.

[1] "sites that due to their geomorphology or vegetation cover characteristics are not able to support certain forms of land use without prejudice to the ecological balance or the natural landscape (Hübner *et al.*, 2004).

Figure 1 Left - Maciço do Morro da Cruz view (red square), in Florianopolis - SC. Right - Monte Serrat community (green square) and Nova Descoberta Street (red polygon). Source: Santa Catarina (2012); Florianopolis (2014) and Salomé (2014).

This research was carried out in a descriptive method based on environmental indicators (Gil, 2008). Given the complexity and breadth of the subject, the scope of the evaluation was limited to the aspects of integrated water management (IWM) to demonstrate the application of the proposed evaluation criteria. Environmental sustainability principles and indicators were identified based on the approach used by Belo Horizonte (Belo Horizonte, 2002 in Bennet, 2004), Florianopolis (CECA, 2001 in Bennet, 2004) and Andrade and Lemos (2015), and separated into five topics: Water Supply; Sewage; Rainwater; Water Source, and Wastewater.

Belo Horizonte (2002 in Bennet, 2004; Sattler, 2015) created a mathematical model to obtain a final index for a planning unit within the municipal territory. CECA (1999 in Bennet, 2004; Sattler, 2015) proposed indicators to measure socio-environmental quality in the city of Florianopolis, considering the specificities of the city, such as its island condition, its geomorphological and environmental characteristics. Finally, Andrade and Lemos (2015) developed environmental indicators based on principles on the quality of urban morphology and green enterprises certification.

Field data was collected from September to November 2016, followed by the analysis of public documents and literature review. The data were later arranged in dichotomous variables (yes or no). Lastly, specific recommendations found in the literature regarding environmental impacts derived from urbanization were selected to assess the situation of the study case.

Results and discussion

Based on the five sustainability indicators regarding aspects of integrated water management (IWM), Table 1 shows the result of the evaluation of the Nova Descoberta Street.

Table 1 - Evaluation of the Nova Descoberta Street with a focus on integrated water management (IWM).

ENVIRONMENTAL INDICATOR OF SUSTAINABILITY	PERFORMANCE			
	NO	NOT APPLICABLE	YES	COMMENTS
1 Water Supply				
1.1 Treated water supply			x	Interviews revealed a 100% of houses have potable water supply.
1.2 Remote water withdrawal			x	About 30 Km from the study site.
1.3 Self-sufficiency	X			This region needs to import water for its livelihood.
2 Sewage				
2.1 Sewer network availability			x	Interviews revealed a 100% of houses are connected to public sewer network
2.2 Decentralized sewage treatment incentive program	X			The water and sanitation company only recommends residents build a sump or sink.
3 Rainwater				
3.1 Natural systems for rainwater retention	X			Techniques used are traditional, so unfiltered water are drained through pipes directed to the local stream.
3.2 Collection and storage of rainwater in public spaces and buildings	X			There are no natural or artificial systems for rainwater retention. There is not rainwater harvesting and storage in public spaces and buildings.
4 Water Source				
4.1 Respect for the natural condition of perennial and intermittent watercourses and recovery of streams	X			The existing stream in the locality was channeled in order flow under the houses. The drainage system leads the rainwater to this stream.
4.2 Respect to topography and streams like boundaries between neighborhoods	X			The design of roads and blocks does not follow the contour lines. The design is not linked to green infrastructures.
5 Waste Water				
5.1 Ecological treatment of wastewater	X			There is no treatment of wastewater.
5.2 Wastewater reuse for non-potable uses	X			There is no wastewater reuse.

For evaluation purposes, the case study was divided in two sectors (Figure 2). In the first sector, the road is flat (between the red and blue arrows, 150 to 140 m) and the street was partially paved with permeable material. The site is steep in sector 2 (between the blue and yellow arrows, 140 to 105 m), and public spaces were completely waterproofed.

Nova Descoberta Street today has a network of water supply, sewage and drainage (Table 1, items 1.1). This represents an upgrade in terms of basic sanitation when it comes to precarious settlements.

However, the project was not conducted in a sustainable manner concerning the hydrological cycle. Serious issues regarding the Florianopolis' water supply system were detected: insufficiency in water supply, the inexistence of a permanent program to protect underground and surface water sources; lack of grants for water abstraction from springs and of an environmental license for the operation of the station; lack of water resource plans for the regional watersheds; inadequate water treatment system; absence of a sanitary permit for the treatment laboratory operation; inaccurate available water volume data; water wastage during transportation or due to clandestine connections (43.31%); inadequate system maintenance; old equipment and water wastage by consumers (TCE/Santa Catarina, 2011).

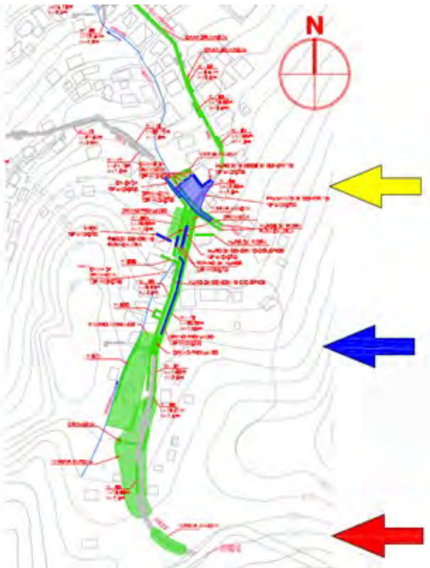

Figure 2 Topographic map of Nova Descoberta Street (between the blue and red arrows, sectors 01 and 02). Source: CGU, 2016.

For Rueda (1999), a model of sustainable water management needs the following principles: the reduction of the extraction of natural resources; the reduction of the pollutant load discharged on the basin; actions for the water economy; reuse of treated water; the use of rainwater; and the reduction of pollutants produced by the discharge of physical, chemical and biological agents into the aquatic environment.

According to Ellis (2010), hydrology must be considered before planning a space intervention so that any settlement can be self-sufficient in water supply (Table 1, items 1.2 and 1.3). This author defends that the Low Impact Development (LID) project is more adequate and cheaper than the conventional urbanization found in Nova Descoberta Street. The LID approach helps to maintain and strengthen the hydrological system of river basins, minimizing the waterproofed surface area, preserving natural vegetation, and reducing the pollutant effluents with local water treatment.

The city's undersized drainage infrastructure was built in the 1970s without a complete urban drainage plan, with shallow runoff and no catchment wells in some parts (Florianópolis, 2015). Nova Descoberta's rainwater drainage network was finished recently and was partially done through concrete pipes, or retaining stony walls. Both mechanisms lead the storm water directly to a local stream. There are no public or private reservoirs for storm water retention, filtration and harvesting (Table 1, items 3.1 and 3.2), despite the existence of a municipal norm that requires that recent buildings must have rainwater reservoirs.

In Florianopolis, some watercourses were straightened, channeled and silted due to lack of proper maintenance (Florianópolis, 2015). In Nova Descoberta, retaining stony walls were built along the local stream and the houses remained close to its border it. Rainwater washes off the street directly into the stream due to the inexistence of Green Infrastructure or other mechanism to retain and filter rainwater before it reaches the watercourse (Table 1, items 3.1). The local stream could have been protected from the impacts of washed-off toxics and pollutants that flow directly in to the stream with the unfiltered rainwater if the public sector had used the LID approach in the area.

In sector 2, land parceling does not follow the natural (topographic) contours of the site (Table 1, items 4.1 and 4.2), sidewalks are absent, and public spaces were waterproofed with concrete (CGU, 2014; 2016). Waterproofing urban soil changes the hydrological cycle, reduces infiltration and groundwater recharge, and increases runoff from rainfall, floods, and pollutant and sediment wash off (Ellis, 2010; Niemczynowicz, 1999). The Treatment Train (Ellis,2010) would minimize the impacts on the water resources in the community. This technique combines Best Management Practices (BMP) and Green Infrastructure by adding different aspects of storm water treatment using vegetation and high drainage covers to intercept, infiltrate and store rainwater (Ellis, 2010; Le Costumer *et al*., 2012; Niemczynowicz, 1999).

In Florianopolis, the sewage network covers around 40% of its districts (Florianópolis, 2015). Individuals or communities try to supply the deficit by building their own septic tanks, infiltration valves or direct launch (Florianópolis, 2010). Due to the recent urban improvements mentioned in this study, Nova Descoberta's sewage network is now connected to a central station, located in the insular part of the city. However, some of the houses in the community are not connected to the public sewage network yet because the responsibility for houses connections belongs to the owners. (Table 1, items 5.1 and 5.2). In addition, the operational capacity of this station was considered outdated in 2012 (TCE / Santa Catarina, 2012).

Farr (2013, pp. 181-189) defends the concept of Living Machines as an alternative to sewage treatment. This author states that these devices are ecologically based equipment, built inside greenhouses. Living Machines, in addition to filtering water, do not use chemicals and allow the reuse of water from the local sewer. Its design also permits the creation of green areas of multiple use, in which it is possible to grow plants, flowers, raise fish, make water sets and extract nutrients for specific purposes.

According to Niemczynowicz (1999), pollution control for water treatment directly on the polluting source facilitates the adaptation of the system to the type of effluent. Therefore, technologies that involve natural biological systems would be suitable for local water treatment in the community (Ellis, 2010; Niemczynowicz, 1999), and temporary water storage could be achieved through swells (Niemczynowicz, 1999). Such devices, as observed by Le Costumer *et al*. (2002), are more cost-effective and durable than traditional filters in removing pollutants and improving water quality and would integrate easily with the urban landscape.

Conclusion

Several authors state the necessity of urban planning combined with hydrology, rainwater management through biofilters, wastewater treatment at the site of the pollutant source, green infrastructures, the combination of traditional water treatment infrastructures with BMPs, rainwater storage and wastewater reuse, as well as the reduction of impermeable areas. However, the construction of the Nova Descoberta Street was carried out without the adequate low-impact environmental design and the government's urban works design completely disregard the environmental vulnerability of the area. Additionally, other problems are worth mentioning: waterproofed public spaces, the lack of sidewalks, disregard for the natural topography of the area in the design of roads and lots, the inexistence of green infrastructures to allow rainwater detention, retention and infiltration, the absence of a local water treatment system and wastewater reuse system, absence of measures to preserve the local stream, and the inadequate hydrological support capacity to sustain the local population.

From an audit's point of view, the recommendation would be to review the suitability of the land-use criteria defined for Nova Descoberta Street and the urban works carried out in the area. It would also be necessary to identify soil disturbance limits, to review land parceling to minimize earthmoving and waterproofed areas surfaces, to use greater drainage capacity coating materials on paved places, to recover and protect the surrounding vegetation and local stream, to include multifunctional and ecological devices to retain, filter and store rainwater, to install wastewater local bio filters and encourage its reuse, and to control erosion and sedimentation. Such measures would mitigate impacts on the hydrological cycle, reduce pollution and urbanization costs (Ellis, 2010; Niemczynowicz, 1999; Le Costumer *et al*., 2012).

The aforementioned methods should not be merely alternative. According to Falkenmark (2011), people need to review water management solutions, and governance strategies should include a more holistic approach. It is important to make stakeholders aware that urban development must combine environmental protection to maintain ecosystem services and sustainable habitability. Public works audits are a useful vehicle for disseminating such ideas as long as they also show the need to implement or reformulate public policies.

However, the results of this research showed that Brazilian public urbanization policy has much to improve regarding sustainable water management. Therefore, more research should be done to improve audits procedures that combine legal, technical and financial compliance analyzes with environmental sustainability assessment. This study also showed that the use of environmental indicators in audit plans is a flexible method that can be applied to any country, where environmental indicators can be selected according to the specific needs of the site, the projects and works that will be analyzed.

Abstract: In recent years, the frequency and impact of flash floods in Mediterranean coastal towns has substantially increased and will continue to rise due to a combination of Climate Change and anthropogenic factors. In 2007, one Spanish town was tragically affected by the Girona River floods, which in few hours severely damaged and destroyed entire buildings. However, despite the severe psychological, physical and economic loss that the population suffered, there is insufficient information and awareness on the risks of recurrence of this phenomenon and the threat that it represents. Previous research studies have proposed to free the riverbed by demolishing buildings and create more green areas. However, an architectural and environmental design approach to retrofit and adapt the damaged housing in order to improve their resilience to extreme climatic events, has never been proposed. The aim of this project is to identify sustainable adaptation strategies for the design and construction of housing buildings affected by the floods. The following studies demonstrated that a series of mitigative and adaptive strategies can be successfully applied not only to prevent flooding and water ingress into building, but also to improve interior environmental conditions in order to maximise comfort and minimise heating and cooling energy demand.

Keywords: Flash-floods, retrofit, sustainable-adaptation, energy-demand.

Introduction

In October of 2007, a huge catastrophe hit the town of El Verger, located in the Valencian Community, Spain. Very strong and torrential rain fell into the higher altitude areas of the Girona river basin due to the *Cold Drop* phenomenon (Camarasa, 2009). The river overflowed in the floodplain area, where several towns are located.

This was not an isolated case, as the Valencian Community is historically one of the regions most affected by flash floods in Spain (Insurance Consortium of Geologic and Mining Spanish Institute, 2006). One of the most important and famous cases is the 1957 flood in Valencia, which completely destroyed the city and killed hundreds of people (J.J.S.I., 2011). It was a catastrophe without precedents, and due to the unexpected consequences of the floods, the Government at that time made a radical decision to dry the Turia river basin on its way through the city (Angus Baker, 2013). Nowadays, this feature makes Valencia the only city in the world to have its green core, activity, and cultural hub located inside an old river basin.

Thus, this project is based around the common and important issue of flash flooding, which due to climate change and human action, will become more and more frequent in the future. Can architects improve the situation and reduce the negative impacts of extreme weather events and increased building construction and urban densification through a climatic and environmentally responsive perspective?

Following a literature review and background research on the responses by local hydrology experts, one of the proposed solutions (Palencia, 2015) was to remove all buildings inside the danger zone, and create green areas around the river, which would absorb rain water and reduce runoff considerably. However, this solution is quite unrealistic and difficult to implement. Apart from the obvious economic impediments, it would have a high-impact on the population. Residents would be required to leave their family houses, and would lose not only their homes but a huge part of their memories and life moments. Nevertheless, another solution, more sensitive to the social context and feasible was proposed and analysed: to **retrofit of the existing housing stock to improve their resilience and comfort conditions**. A good explanation of all problems and consequences of this research can be found in Fig. 1.

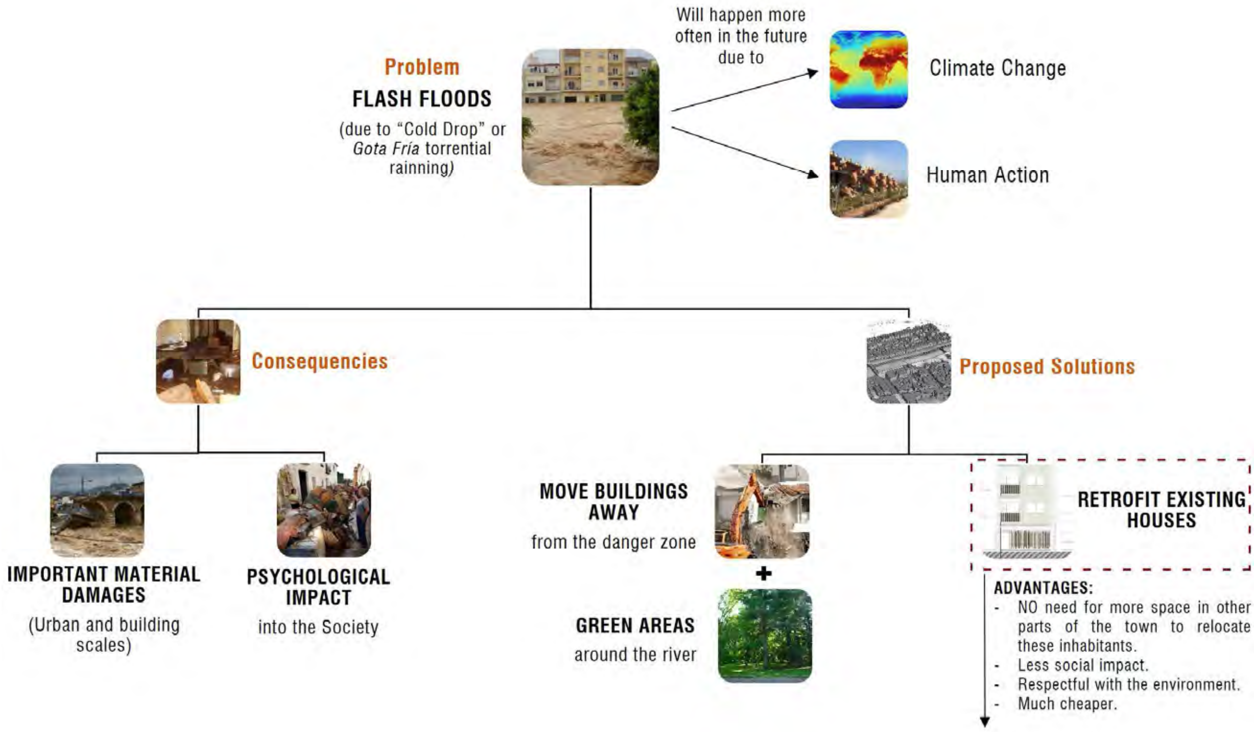

Figure 1. Concept diagram of the main problem, consequences and proposed solutions of El Verger 2007 floods.

Urban Context. El Verger Historic Urban Growth

The Girona River has always been the articulatory axis of El Verger, and the first settlements were located in the area where the church is currently placed. This is precisely located on the highest point of the town, which means that our ancestors were aware that this would be the safest place.

The two maps on Fig. 2, demonstrate that urban density in 1955 was highest on the West part of the river, and the urban tendency during the last 50-60 years has been in the same direction. However, building development started to grow on the other side of the river at that time too, and now these structures shape an important part of the total urban area of the town. In Fig. 2, the urban sections of 1955 and 2016 show this urban density change, especially on the East side of the river. Further, it is important to see how human actions have transformed the riverbed basin. Before it had natural slopes on both sides, and now reinforced concrete walls have been placed, and the width has narrowed.

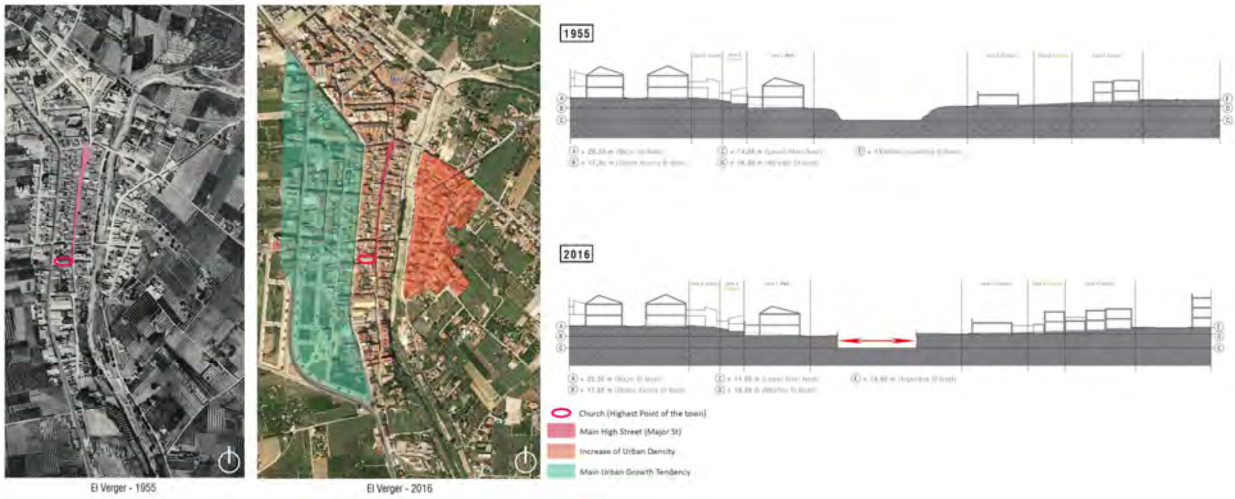

Figure 2. Historic (1955) and present maps of El Verger and urban sections of these periods.

Urban Context. Present

The Planning Authority of El Verger stablished after the 2007 floods, 4 flooding zones depending on the flood water level arrived to every building (El Verger Urban Council, 2015). The first zone is red and it represents the most affected buildings. The level of the water reached the first floors (around 3 m high). The orange zone includes the second most affected buildings and the water reached between 2 and 2.5 m high. The yellow zone is the most reduced zone and the buildings experienced a medium level of flood water, between 1 and 2 m high. Finally, the green zone, includes a large number of houses, which were less affected, but still suffered lots of physical damages. The level in this zone reached 1 m high or less. Based on this zoning, two case studies were chosen as part of this study to investigate more deeply their issues. One case is located in the red high flood risk zone (Case Study 1, a terraced single-family house) and one in the orange zone (Case Study 2, a terraced apartment building), both marked on Fig. 3 (urban cross sections with and without flood water) and Fig. 4 (urban plan of the studied area with floods zones shaded).

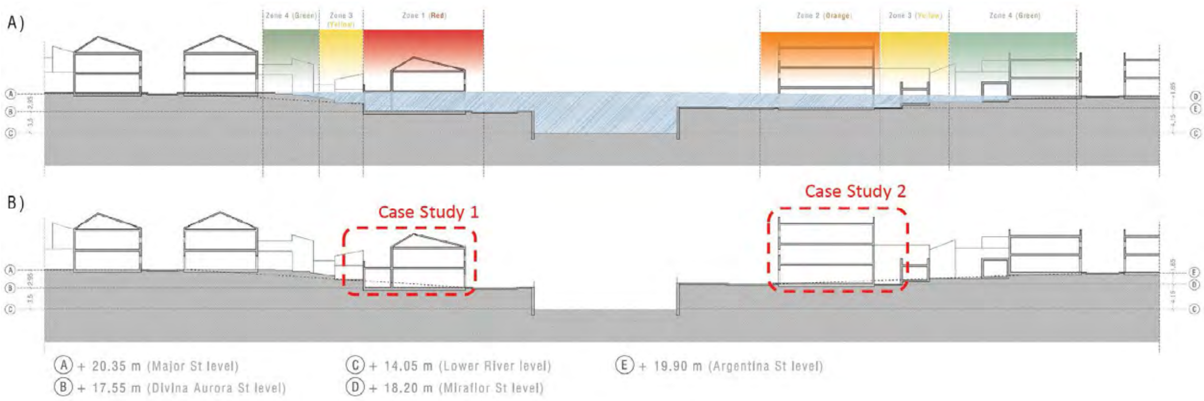

Figure 3. Urban cross section of El Verger indicating (A) flood zones and colour classification; and (B) the two case study buildings.

Figure 4. Urban plan of El Verger indicating flood zones and colour classification.

Climate Analysis

El Verger is included into the mild Mediterranean climate area and as such it presents these general features: a) very mild winters, softened by the sea action; b) long, dry and very warm/hot summers; c) almost 3.000 hours of sunshine per year; d) precipitations in spring and autumn; e) very strong precipitations risk (*Cold Drop*) in September and October; f) No precipitations in the rest of the year; g) High relative humidity (average 65 %); h) Optimal number of hours of daylight (ref). As shown in Fig. 5, where the Valencia Cumulative rainfall is explained comparing present and A1B Future Scenario in 2050, due to climate change, a general reduction in precipitation will be experienced throughout the year. Moreover, the main precipitation data will be concentrated in October creating a “dangerous peak”.

Figure 5. Valencia Cumulative Rainfall: Present (left) and A1B Scenario in 2050 (right). (Meteonorm 7).

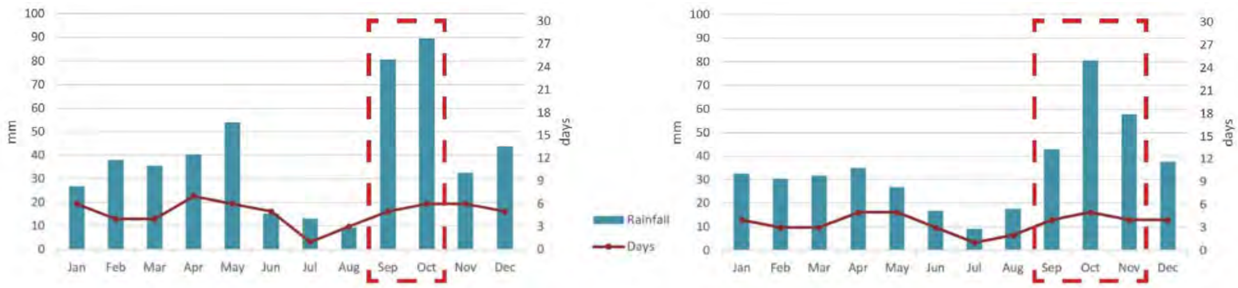

Figure 6. Valencia Relative Humidity: Present (left) and A1B Scenario in 2050 (right). (Meteonorm 7).

Building Scale Analysis

Considering the most typical building typologies affected by 2007 floods and El Verger population pattern, the following cases were selected: 1) one terraced single-family home with one traditional family and 2) one apartment building with one widow grandmother and a single mother with two daughters. Considering all the problems and risks these buildings are exposed to, and after having a broad idea of which are their environmental and climate conditions, one of the most important things to be outlined will be the strategies to be applied. Based on literature review, precedents, fieldwork and urban analytic work findings, the following case scenarios collected on Table 1 have been chosen as best ideas.

Table 1. Cases table which the main design proposals and where are going to be tested, together with the best zones to be applied to.

Case n.	Leaves the water coming inside the building?	Tested on	Best Zones to be applied to
CASE 1. Leave the GF as a semi-open space & move residential spaces to the upper floors + Raise one step the GF and make a drainage floor system	Yes	Case Study 2 Terraced Apartment Building	Zone 1 (Red) Zone 2 (Orange)
CASE 2. Shell around the GF walls + Composite Flood Doors & Windows	No	Case Study 1 Terraced Single-Family House	All zones
CASE 3. Raise two steps the GF level on a Suspended Floor + Optional Case 2	No	Case Study 2 Terraced Apartment Building	Zone 3 (Yellow) Zone 4 (Green)

Design Applicability

Two different techniques were proposed to allow the water being drained easily through the ground and to avoid the damp water rise through the walls or other building elements.

Figure 7. Two steps and a high suspended floor (right) and one step and gravel drainage floor (left) sections.

The first one would be a) to build two steps and a high suspended floor (Case 3, Table 1); and, b) to rise one step into the GF level and create a gravel drainage floor (Case 1, Table 1). Also, compare both strategies on Fig. 7 building sections. Both options are feasible because the current ceiling height is 3.2 m and one of these techniques will only take 0.36 m. Apart from this, the GF doors would be composed by open wooden slats to allow the water coming in (in both façades) (see Fig. 8).

Figure 8. Virtual images of the of the proposed flood resilience design for Case Study 2: Terraced Apartment Building, with and without flood water, as it would be most of the time.

Daylighting Studies

Apart from solving the flooding problems, one of the main goals of this research was to carry out at the same time a sustainable retrofit of the houses affected. One of the important things to reduce the energy demand of the buildings are the daylighting studies. A considerable improvement will be achieved by modifying the interior layout of the apartments. As an example, Case Study 2 apartments have their dining-rooms with no openings to the exterior and they are completely dark and poorly ventilated (Daylight Factor = 0%). Additional strategies will be also applied such as: 1) increase the window to floor area in both elevations (from 7.81% (East) and 9.21% (West) on the main bedrooms to 15%;

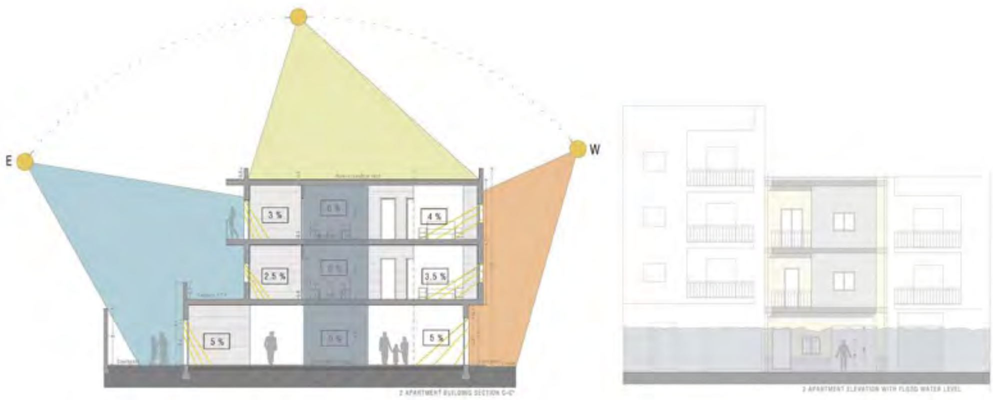

Figure 9. Current section with daylight factor percentages and solar radiation plotted, together with the current elevations with the flood water level arrived to this building in 2007 floods.

2) add two skylights above the staircase; and, 3) build a glass partition into the corridor of the apartments entrances (which before was also completely dark, DF = 0%). Fig. 9 and Fig. 10 illustrate the current and proposed strategies in section and elevation, respectively.

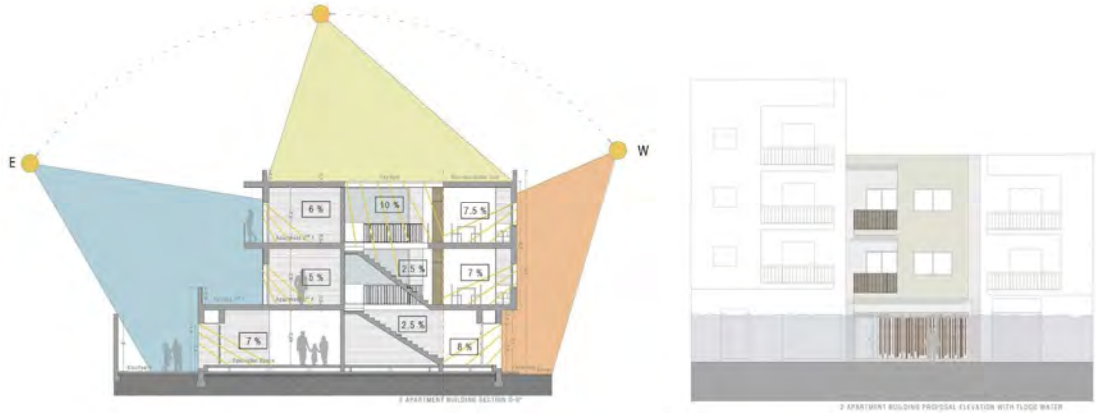

Figure 10. Proposed section with daylighting percentages and solar radiation plotted, together with the proposed elevation with the flood water level arrived to this building in 2007 floods.

Ventilation Strategies and Thermal Performance

Another important aspect to have into consideration to improve the comfort conditions of the interior of the houses and also to reduce some levels of uncomfortable relative humidity, will be to apply several ventilation strategies. Same as before, this will be important to carry out a sustainable design refurbishments. These ventilation strategies are based on cross ventilation (CV) plus stack ventilation (SV) through the stairs skylight, recording before less than 10 ACH (Buoyancy + Wind Driven) and more than 45 ACH after the strategies applied (almost achieving the necessary for cooling on hot seasons). See Fig. 11 to understand this ventilation strategies in Case Study 2 (Apartment Building). This will also be related to thermal performance, because good ventilation levels can reduce significantly the overheating inside of a space and consequently the need for air conditioning (and therefore the energy demand). Thus, the temperatures will drop from more than 30-32°C (in summer) or rise from 12-14°C (in winter) on current situation to be between 19°C to 21°C in all seasons of the year (considered to be inside the comfort band) (see Fig. 12).

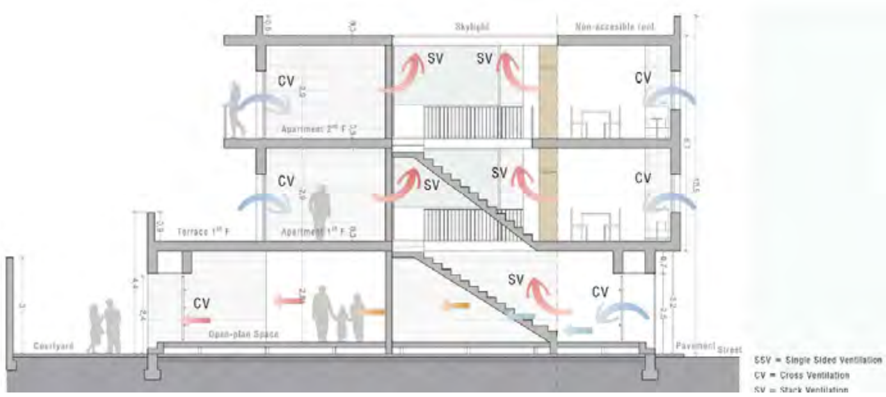

Figure 11. Section of the proposed ventilation system in Case Study 2 (Apartment building) and the different air movements plotted.

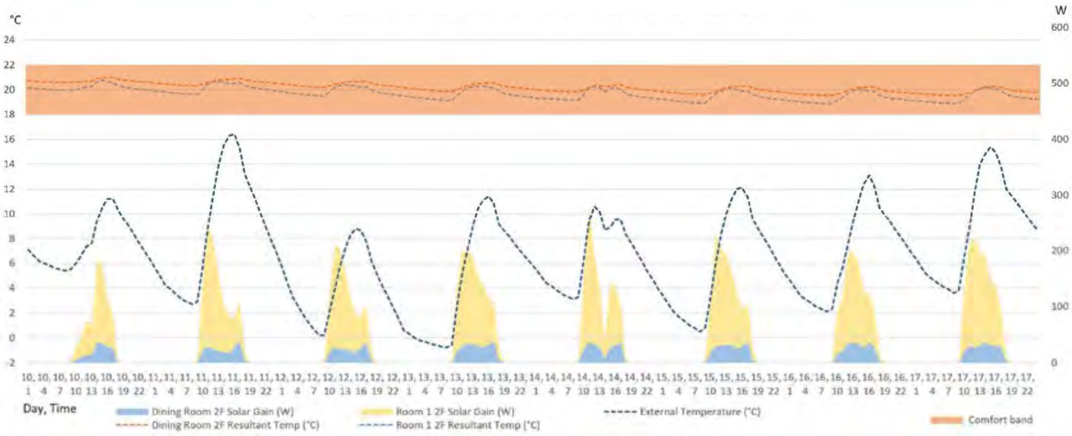

Figure 12. Thermal performance of this case scenario in some of the interior rooms (10-17th January).

Conclusion

Cold Drop affects to all eastern Mediterranean areas and landscape features are almost identical in all cases (relative short river basins with pronounced height difference between its source and mouth). Design interventions studied on this research show that by applying simple strategies to buildings, reducing paved surfaces, creating more interior courtyards, etc. we can significantly reduce the flood damage; and, most importantly, without moving any house or inhabitant. Then, at the same time, if these strategies are made from a sustainable point of view, we can bring all the occupants into a comfort situation almost all year round inside the interior spaces, just changing the W to F ratio, materials or ventilation habits (as we have seen on last sections).

Abstract: This paper seeks to understand water use and identify potential water savings for different water conservation strategies in a specific type of school in the Federal District, Brazil. A correlation analysis using quantitative data on metered water consumption, population, built area, built age, garden area and number of sanitary appliances was carried out to understand the main variables that affect water demand in schools. A water audit was carried out in an educational centre to obtain qualitative data on fixture and appliance flow rates, water use habits and water end-uses. With both quantitative and qualitative data-sets, a representative model was composed in order to estimate potential water savings for water efficient equipments and rainwater harvesting systems for non-potable uses. Overall, findings suggest that garden and built area are the most relevant variables that affect school water consumption. Results from water auditing demonstrated that the highest rates of water consumption correspond to leaks (27%) and garden irrigation (24%), suggesting that the main water efficient strategies involves the repair of plumbing leakage and use of sprinklers for irrigation, promoting an annual saving of 681 m^3/year and 1.808 m^3/year respectively. Rainwater harvesting systems were capable of promoting water savings up to 287 m^3/year.

Keywords: Water use, Water efficiency, Rainwater harvesting, Public school

Introduction

The Federal District is under water stress and because of this, the local government determined that all public buildings should reduce their water consumption to a minimum 10% (GDF, 2016). Educational centres represent 15% of all public schools in the Federal District (SEDF, 2013). Hence, it is crucial to identify optimal water saving strategies for an effective water conservation programme in public schools.

Few studies have been carried out regarding water use and conservation in educational institutions in Brazil. (Ywashima, 2005) argues that part of the water consumption in many school buildings is due to leaks and losses. According to the author, one of the main reasons for this, is that managers do not have access to the water bills; these are paid directly by the government. In a later study, (Ywashima et al., 2006) identifies the main water efficient strategies for promoting water conservation in a public school in Campinas. (Ghisi and Marinoski, 2008) conducted a survey that estimated water end-uses at a school in Florianópolis. Based on the data collected, potential water savings were estimated for different rainwater harvesting systems.

The detailed understanding of school water consumption patterns makes way to both development and evaluation of water conservation programmes. Quantifying the amount of water consumed by each individual water fixture and appliance in a school allows us to accurately identify inefficiencies, consumption 'hot-spots' and the uses that offer the greatest conservation potential. However, according to (Vieira et al., 2007), water consumption can vary considerably depending on several factors, such as population, climate, socioeconomic backgrounds and cultural habits. Public schools from the Federal District presents different characteristics from those in previous studies. There is a lack of a data base on water end-use indicators and information on potential water savings for different water conservation strategies in public schools - more specifically, in educational centres of the Federal District. With this in mind, the main objective of this study was to understand water use and identify potential water savings for different water conservation strategies in educational centres of the Federal District, Brazil.

Methodology

As a starting point, a quantitative data was collected by means of remote sensing, on-site observations and questionnaires directed to school directors and building managers for 18 educational centres to collect primary data on metered water consumption, population, built area, built age, garden area and number of sanitary appliances. A correlation analysis using quantitative data on metered water consumption, population, built area, garden area and number of sanitary appliances was carried out using Pearson's correlation coefficient to understand the main variables that affect water demand in schools.

Then, a water audit was carried out in an educational centre, *Centro Educacional 04* (CED 04) in *Guará*, Federal District. Metered water bills were provided by building manager from January 2011 to December 2014 to verify school water consumption. Qualitative data on fixture and appliance flow rates and water use frequencies were used to estimate water end-uses. A full inventory of appliances, fixtures and other water-consuming features was carried out in order to identify sources of water usage, quantify their flow rates and detect any visible leaks. The flow rate of every tap-opening fixture was identified by measuring the time it took to fill up a one litre container by opening the tap half a turn in order to obtain the average flow of a tap, thus obtaining its flow rate. Flow rates of toilets were estimated according to the basin's flushing volume. Toilet flushing and bathroom faucet use frequencies per person were obtained via *in-situ* observations, while kitchen faucet use frequencies were filmed on camera and floor washing and garden irrigation frequencies were obtained through the use of questionnaires.

With both quantitative and qualitative data-sets, a representative model was composed in order to estimate water savings from water efficient equipment and rainwater harvesting systems. For this study, only commercially available water efficient equipments in Brazil were considered for analysis. These included, flow restrictors, automatic bathroom faucets, dual-flush toilets, efficient dishwashers, pressure washers and sprinklers for irrigation. Overall, water savings for these strategies were determined according to their potential water savings, reduced flow rates or consumption loads. In order to analyse the potential water savings from rainwater harvesting systems, three types of non-potable demands were considered for analysis: irrigation and floor washing (Scenario 1); toilet flushing (Scenario 2); and irrigation, floor washing and toilet flushing (Scenario 3). For each of the above rainwater demands, simulations based on daily time intervals using the behavioural model in Equation 1 with a yield after spillage operating rule (Equation 2) for a series of storage volumes was carried out in order to identify water savings for an array of rainwater tank sizes. Three catchment areas were considered according to filter treatment capacity: 200m²; 500m² and; 3000m².

$$V_t = V_{t-1} + S_t - D_t \tag{1}$$

Subject to $0 \leq V_{t-1} \leq C$
V_t = Storage volume at time interval, t
V_{t-1} = Storage volume at time interval, t-1
S_t = Supply during time interval, t
D_t = Demand during time interval, t
C = Storage capacity

$$Y_t = \min \begin{cases} D_t \\ V_{t-1} + S_t \end{cases} \tag{2}$$

$$V_t = \min \begin{cases} V_{t-1} + S_t - Y_t \\ C \end{cases}$$

Y_t = Yield during time interval, t

Results

Based on metered water consumption data obtained from water bills, it is possible to observe a 43% growth in water consumption between 2012 and 2014 (Figure 1). The correlation analysis serves as empirical indications of possible relationships between variables and measure the degree of linear association between two variables. Results shown in Table 1 indicates that water consumption had a very strong relationship with garden area (0.69) and built area (0.64). These correlation coefficients are significant at the 1% or 5% level, that is, they are statistically significantly different from zero at 99% or 95% level of significance. Built age and number of sanitary appliances did not present a relationship with water consumption. Interestingly, population did not present a strong relationship with water consumption (0.30).

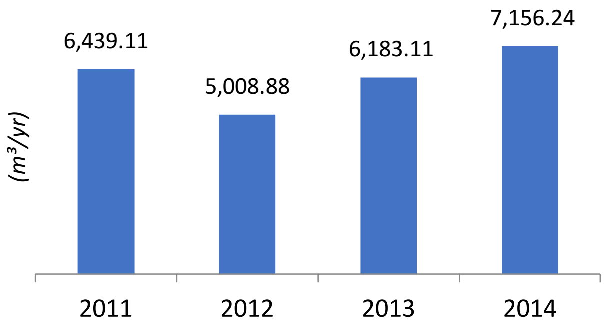

Figure 1: Annual water consumption from 2011 to 2014.

Table 1: Correlation between different water consumption variables.

	Consumption	Population	Built Age	Built Area	Garden Area	Nº Toilets
Consumption	1					
Population	.304	1				
Built Age	.173	.003	1			
Built Area	.643**	-.134	.261	1		
Garden Area	.694**	-.303	.147	.815**	1	
Nº Toilets	-.033	-.299	-.220	.368	.365	1

Table 2 below summarizes values related to the final uses of water in the Guará CED-04, where the estimated consumption for the various water-sanitation equipment of the school was obtained, as well as the values related to losses and leaks. Taking into account the hydraulic audit carried out in the school, the corrected values were also obtained, using a correction factor equivalent to 0.10 based on the difference between the estimated consumption (by the hydraulic audit) and the measured consumption from water meter.

Table 2: Estimated and corrected water end-uses.

END-USES OF WATER CONSUMPTION	Estimated	Corrected
Sanitary Discharge	1416 liters/day	1271 liters/day
Washbasin	203 liters/day	182 liters/day
Drinking fountain	115 liters/day	103 liters/day
Kitchen Sink Faucet	1626 liters/day	1459 liters/day
Irrigation	1747 liters/day	1568 liters/day
Cleaning	244 liters/day	219 liters/day
Losses and Leaks	2005 liters/day	1799 liters/day
TOTAL	7,355 liters/day	6,600 liters/day

There is a predominance of uses related to losses and leaks (27%), irrigation (24%) and sanitary discharges (19%). These three uses correspond to 70% of the total water consumed daily in CED-04, being equivalent to 4,635 litres/day (4,6m³/day). Floor washing and cleaning in general and drinking fountains contribute little to the daily consumption of water at school, accounting for only 5% of daily water consumption (322 litres/day). Water consumption indicators help in understanding the relationship between the quantity of litres of water spent and the population of a given place (consumption *per capita*).

Table 3: Water saving equipment.

Water saving equipment	Amount	Reduction Potential (%)		Base Consumption (m^3/ano)	Reduced Consumption (m^3/ano)	Water economy (m^3/ano)	
Automatic Faucet Sensor with Flow Reducer	9	83	*	490	83	407	
Double Discharge Valve (3/6 lpf)	12	30	*	1099	773	326	
Tap Water Faucet with Flow Restrictor	3	88	*	618	74	543	
Flow regulator	2	28	*	322	232	90	
Industrial Washers	1	99	*	322	3	318	
High pressure washer (2100 W)	1	67	*	37	12	24	
Sprinkler "ECO rotator"	85	87	*	2078	270	1808	
Leaks Repair	---	100	*	681	0	681	
* Based on manufacturer's specifications				5324	1448	4198	**TOTAL**
				100%	27,2%	78,8%	**%**

Solutions to reduce water consumption in schools in the Federal District involve the implementation of water saving equipment, which represents an alternative of greater economic, technical and environmental feasibility for its implementation, such as: flow restrictors and regulators, tidal aerators, double-flush and the automation of the faucets of lavatories and water fountains. For study purposes, the reduction potential, the base consumption, the reduced consumption and the water saving take into account only one equipment per category / environment.

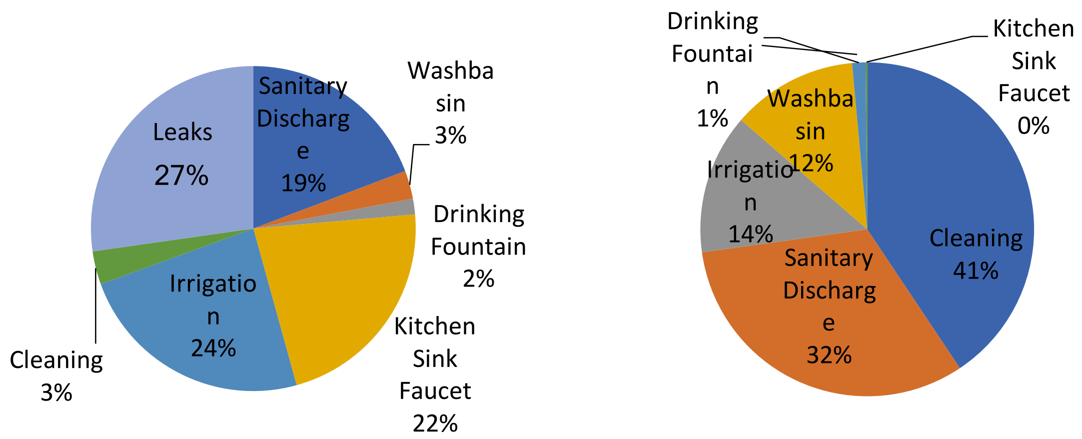

Figure 3: Comparison of end-uses without and with economizing equipment.

Table 4 presents a comparison between the current consumption, called the base consumption, based on the values of the final uses of water corrected and the future consumption, called reduced consumption, based on the values of the final uses of water obtained with the implantation of saving equipment. At first, the comparative table explains the benefits of the implantation of water saving equipment: activities that require the use of water for non-potable purposes are responsible for a daily consumption of 9.229,65 liters (9.3 m^3/day) and after Implementation of the economizadores equipment, the consumption happens to be only 4,714 liters (4,7m^3/day), which represents a reduction of 49%, only with small changes in the existing hydrosanitary equipments in the school.

Table 4: Current consumption (base) and proposed (reduced) water.

Base Consumption		Reduced Consumption	
Scenario 1 ***(liters/day)***		**Scenario 1 (liters/day)**	
Garden Faucet	6.721,24	*Garden Faucet*	2.958,20
TOTAL	**6.721,24**	**TOTAL**	**2.958,20**
Scenario 2 (liters/day)		**Scenario 2 (liters/day)**	
Sanitary Discharge	2.508,41	*Sanitary Discharge*	1.755,89
TOTAL	**2.508,41**	**TOTAL**	**1.755,89**
Scenario 3 (liters/day)		**Scenario 3 (liters/day)**	
Sanitary Discharge	2.508,41	*Sanitary Discharge*	1.755,89
Garden Faucet	6.721,24	*Garden Faucet*	2.958,20
TOTAL	**9.229,65**	**TOTAL**	**4.714,09**

Subsequently, this comparative serves to compose AAP systems that can supply the reduced, but still significant, demand for non-potable water used to carry out the aforementioned activities. In order to analyze and understand the various possibilities of implementation of AAP systems, three different scenarios were proposed where it would be possible to use such systems: scenario 1 consists only of garden faucets used for floor cleaning and irrigation. Currently the performance of such activity consumes 6,721.24 liters of water per day (6.7m³/day), the reduced consumption represents only 44% of current consumption, with 2,958.2 liters / day (2.9m³/day). Scenario 2 is composed of the current consumption of water directed to sanitary discharges, where it is currently consumed 2,508.41 liters of water per day, and the reduction of 30% in consumption results in daily values of 1,756 liters of water (1.7m³/day). Finally, scenario 3 is composed by the combination of the two previous scenarios, which include the three activities considered for the purpose of proposing AAP systems. The values of the base consumption and the subsequent reduced consumption have already been presented above (2nd paragraph). Based on the composition of these scenarios and the decomposition of the reduced water consumption, it was possible to measure several possibilities of AAP systems, based on factors such as water catchment area of the roofs of the school, capacity of the cistern, based on filtration capacity, and economy of Water (m³/year).

Scenario 1 demonstrates four different simulations: the first is the simulation of the necessary capacity of the cistern for the basic consumption (without saving equipment) with rainwater catchment area of 200m². To achieve 100% efficiency, which corresponds to a saving of 130m³ / year, a cistern with a capacity of more than 59m³ is required: the simulation indicated a cistern with a storage capacity of 109m³. The last simulation of scenario 1 takes into account reduced consumption (with saving equipment) and a catchment area of 200m². Note that in this case the maximum efficiency is reached with a cistern with a capacity of 7m³.

For scenario 2, six simulations were required, since the demand for water consumption for sanitary discharges is higher. The first simulation, with baseline consumption and water catchment area of 200 m², resulted in a water saving of 157m³ / year when maximum efficiency was reached. This would require a cistern with a storage capacity of 50m³. The final three simulations concern the reduced consumption, whose maximum efficiency represents an economy of 110m³ / year. The fourth simulation considers a catchment area of 200m², where maximum efficiency is achieved with a cistern with a capacity of 30m³. The fifth simulation, which considers a catchment area of 500m² requires a cistern with the capacity to store 19m³. Finally, the last simulation for reduced consumption, which considers a catchment area of 3,000m², where a cistern containing only 2m³ of water is needed.

The last scenario is the junction of the first two, so it has a greater demand for water. The first simulation, which takes into account the baseline consumption and a rainwater catchment area of only 200 m^2, did not present plausible results to obtain efficiency Maximum, which corresponds to an annual reduction of 287m³, instead showed a maximum efficiency of only 63%, which corresponds to an annual saving of 180m³ and cistern with capacity for 69m³ of water. The three simulations with the reduced consumption were also satisfactory, since all reached 100% efficiency: the first with a catchment area of 200sqm and a cistern of 46m³. The second with a catchment area of 500m² and a cistern of 29m³ and finally the last simulation, with a rainwater catchment area of 3,000m² and a cistern of only 3m³.

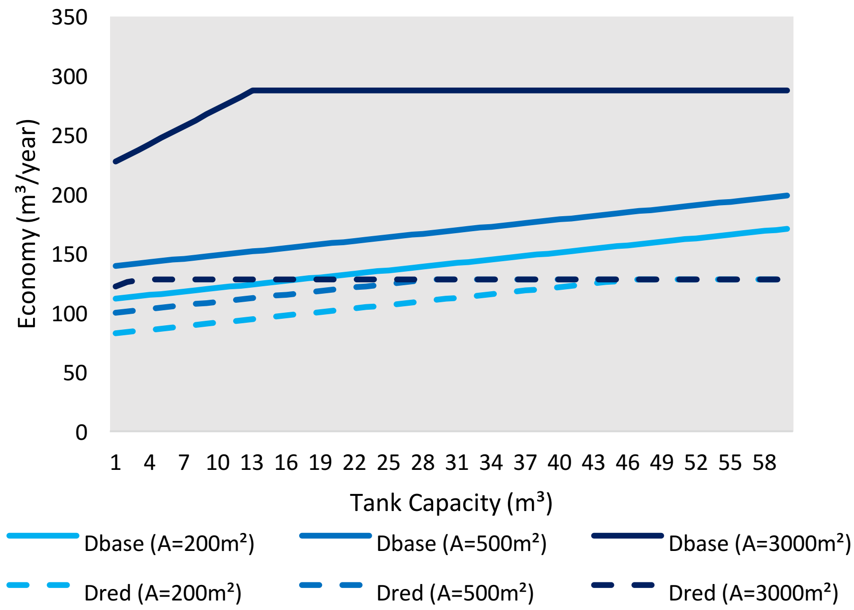

Figure 3: Comparison of end-uses without and with economizing equipment.

Conclusion

With the analysis of qualitative and quantitative data, it was possible not only to identify and categorize end-uses of water and to understand the habits related to floor washing, irrigation and sanitary use. On the other hand, data on end-uses of water made it possible to propose specific water-saving equipment for each activity carried out in the school, in order to reduce water consumption. In addition to the implementation of water saving equipment, the composition of several scenarios that simulate the implementation of AAP systems has increased the potential of reducing water consumption for non-potable purposes.

With the implementation of water-saving equipment in Guará CED-4, a potential reduction of 78.8% in annual water consumption is predicted, which represents an annual value of 4,198m³. Considering the same reduction potential for the other schools interviewed, a water saving of 75,564m³ per year is estimated. This value is extremely significant, since it demonstrates the effective reduction of water consumption with simple measures.

With the reduction of water consumption through the implantation of water-saving equipment, a new configuration of water consumption was achieved in its final uses. Then, it was proposed the implantation of AAP systems in order to utilize the rainwater, currently discarded. The composition of three different scenarios allowed the simulation of different configurations for the same AAP systems. This measure was taken in the future to address as many schools as possible, considering the different typologies of existing buildings and also considering the future financial implications that the implementation of such systems may entail. With the proposition of cisterns with different storage capacities it is possible to make several adaptations that aim to meet the best possible way the individual demands of each school that will make use of this study in the future. Also demonstrating that it is possible to reach the maximum efficiency of the system even in a climate less prone to rainfall, as is the case of the Federal District, which is considered of great importance for future studies in the area, as well as for the real implementation of these systems in several public buildings in the capital.

The present article makes it possible to carry out future studies aimed at deepening the studies already carried out, especially regarding the concomitant use or not of water saving equipment with AAP systems, taking into account the technical, economic and environmental feasibility of each alternative.

Social-Ecological-Technical Systems in urban planning for a Circular Economy: an opportunity for horizontal integration

Janneke van der Leer[1], Arjan van Timmeren[1] and Alexander Wandl[1]

[1] Chair of Environmental Technology and Design, Department of Urbanism, Faculty of Architecture and the Built Environment, Delft University of Technology, Delft, the Netherlands, j.g.g.vanderleer@tudelft.nl

Abstract: Circular Economy (CE) is receiving interest worldwide as a way to overcome the currently dominating linear and wasteful production and consumption model of our environment. Currently the implementation of CE to practice is still in an early stage. As hubs of consumption and to a more limited part also production, metropolitan areas often are seen as crucial to achieve the transition towards a CE. Therefore it is necessary to find ways to integrate a CE based approach in urban planning practice. This paper reviews literature dealing with the concept of CE by making use of a framework for urban planning to evaluate integration of vertical and horizontal dimensions in CE literature. This paper reviews the scales of CE as regarding vertical integration, while for horizontal integration the sub-systems that need to be integrated are investigated. Thereafter, the framework is used to evaluate existing CE urban planning documents of the Amsterdam Metropolitan Area and surroundings.
The paper aims to contribute to the comprehension of the concept of CE for the urban planning practice. This understanding enables urban planners to integrate CE in their work and aims to contribute to further accelerate the implementation of CE in metropolitan areas.

Keywords: Circular Economy, urban planning, integrated approach, SETS, Amsterdam Metropolitan Area

Introduction

Circular Economy (CE) is receiving interest worldwide as a way to overcome the currently dominating linear and wasteful production and consumption model of our society. In the last decades CE has become an important and significant new school of thought in sustainable development aiming sciences (Murray et al., 2015), however the implementation of CE worldwide is still at an early stage of development (Ghisellini et al., 2016) while there are only few studies on the concept (Jurgilevich et al., 2016). Most of the times Circular Economy (CE) is studied and treated only as an approach to more appropriate waste management (Ghisellini et al., 2016). However, CE is more than optimized waste management and could be used to understand and implement new models for sustainability and wellbeing with low or no material, energy and environmental damages (ibid). A comprehensive definition of CE is provided by Murray et al. (2015, p. 377): "an economic model wherein planning, resourcing, procurement, production and reprocessing are designed and managed, as both process and output, to maximize ecosystem functioning and human well-being".

To realize CE on larger scale a radical change, or even a paradigm shift, is needed (Bonciul, 2014; Lieder and Rashid, 2016). The implementation of CE is challenging because of the current linear mind-set and the structures in industry and society (Lieder and Rashid, 2016) and because it requires changes in different sub-systems on various scales (Van Buren et al., 2016). Metropolitan areas often are seen as crucial to achieve the transition towards a CE (Van Timmeren, 2013; Cohen and Muñoz, 2016; Owen and Liddell, 2016) as they are the hubs of consumption and to a more limited part also production, while at the same time the environments that are faced with scarce resources and insufficient infrastructure capacity (McLaren and Agyeman, 2015).

Metropolitan regions can, as every other complex system, be described by the conceptual framework of panarchy (Gunderson et al., 1995; Gunderson and Holling, 2002; Holling et al., 2002) which accounts for the duality of stability and change in which complex systems of people and nature are dynamically organized and structured across scales of space and time (Allen et al., 2014). It is important to find ways to incorporate a CE based approach in urban planning practice (Owen and Liddell, 2016). Urban planning is an integrative discipline: it needs to integrate physical, social-cultural infrastructure, the economy and the environment (Rotmans et al., 2000; Karvounis, 2015). According to He et al. (2011) urban planning can be defined as an interdisciplinary and comprehensive approach for a balanced regional development and physical organization of space. The aim of this paper is to identify possibilities for the integration of CE principles in urban planning.

Methodology

In order to identify how to integrate a CE approach in urban planning it is necessary to understand first the integrative dimensions of urban planning. Urban planning aims to change or manage spatial development by constructing new ideas, visions, actions, means for implementation, processes and other ways of understanding (Albrechts, 2006a, 2006b). It is an integrative discipline in which often two (organizational) dimensions are discerned: horizontal integration and vertical integration (Stead and Meijers, 2009; Holden, 2012). The horizontal integration has the aim to deepen specific knowledge (Albrechts, 2006a) and emphasizes “collaboration, coordination and the building of working relationships” (Albrechts, 2006b) across policy domains, local agencies and departments (Hajer and Zonneveld, 2000; Stead and Meijers, 2009). The vertical integration is related to linkages between different scale levels (Albrechts, 2006b), levels of government, like national, provincial and municipal (Hajer and Zonneveld, 2000) and different tiers of government (Stead and Meijers, 2009). Figure 1 illustrates the horizontal and vertical integration in urban planning.

This urban planning framework is used to evaluate how the concept of CE can be integrated in urban planning, by investigating vertical and horizontal dimensions and related aspects in CE literature. Zhijun and Nailing (2007) introduced the vertical and horizontal dimension in the context of CE and stress the integration of different scale levels vertically and the integration of different sub-systems horizontally for a practical implementation of CE. Based on this approach, this paper reviews the scales and approaches of CE as regarding vertical integration, while for horizontal integration the sub-systems that need to be integrated are investigated. Thereafter, a framework to evaluate which aspects of integration a specific planning document considers is presented and used to classify four existing CE urban planning documents of the Amsterdam Metropolitan Area (AMA) and its surrounding region.

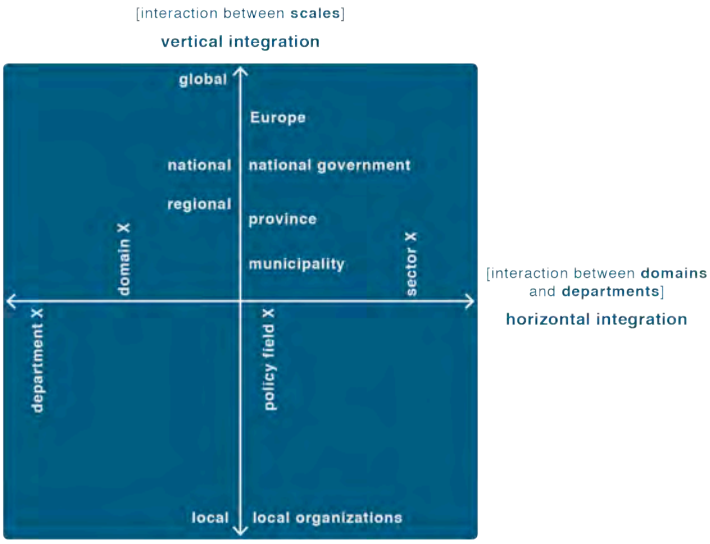

Figure 1: integration in urban planning

Towards a framework to understand opportunities for integration of CE in urban planning
Vertical integration of scales

CE is rooted in environmental economics and Industrial Ecology (Ghisellini et al., 2016). In many CE studies the concept is related to determined spatial scales and these scales are built upon frameworks known from Industrial Ecology (Yuan et al., 2006; Murray et al., 2015). The following three scales can be discerned regarding research in relation to CE: micro level (individual company level), meso level (eco-industrial network level) and macro level (city, municipality, province or state)(Yuan et al., 2006; Ghisellini et al., 2016).

The development of CE has a potential to raise awareness and creativity on a more local level, therefore, adaptive governance may be an important force in the transition to sustainable pathways in cities (Van Timmeren, 2013). A very important result of localization of CE is that the use of resources together with the problems arising from our lifestyles and consumption patterns will become more apparent and transparent to the public at large. Hence, the distance between awareness and action can be decreased (ibid). Therefore, the integration of efforts at all three scale levels is necessary for a successful implementation (Su et al., 2013). However, for material flows and systems, it is hard to determine specific scale levels. As cities are dependent on their (global) hinterland, where extraction and transformation processes take place (Barles, 2014) and for provision of resources, goods and services, it is difficult to determine which scale is specific to which flow (Weisz and Steinberger, 2010). Van Buren et al. (2016) explain that transitions not only need to take place at the regional and national scale, but also at the European and even global scale for implementing a CE. To conclude, the relevant scale to support CE in urban planning depends on the resource flow and the nature of the intervention (Voskamp et al., 2016) and thus often multiple scales and reaches are involved.

Vertical integration of approaches

In some countries, like for instance China, the implementation of CE is a result of a top down approach, while in the transition towards CE in Europe often a bottom up approach is taken (Ghisellini et al., 2016). However, for successful implementation of CE an integration of bottom up and top down approaches seems necessary (Mathews and Tan, 2011; Lieder and Rashid, 2016). It also relates to the 'Sandwich Strategy' by Tjallingii (1996) which according to him is necessary for far-reaching support of the sustainability and perhaps self-sufficiency of the various structures and infrastructures in spatial planning. The strategy distinguishes a basic layer (the users). Decentralized initiatives to solutions and environment-friendly behaviour are emphasized here. These decentralized initiatives are facilitated by the central government, which sets up conditions top-down through goal-oriented system dynamics (Van Timmeren, 2006).

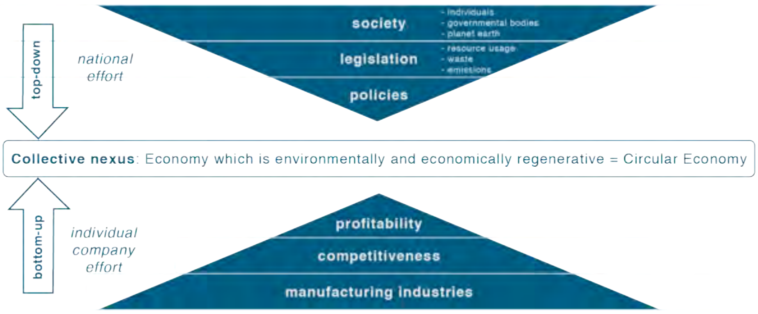

Figure 2: proposed CE implementation strategy applying top-down and bottom-up approach, adopted from Lieder & Rashid (2016)

In the model of Lieder & Rashid (2016), see figure 2, a concurrent approach to implement CE at large scales is proposed. The model is based on the assumption that "inverse motivations exist among the stakeholders of CE which need to be aligned and converged" and is similar to the strategy by Tjallingii (1996). Lieder and Rashid (2016) see top-down as a national effort by society and governmental bodies and bottom-up as the efforts by individual companies.

Horizontal integration of sub-systems

In recent CE literature, the integration and redesign of four sub-systems is mentioned regarding CE in cities, provinces or regions (Zhijun and Nailing, 2007; Ghisellini et al., 2016): the industrial system, the infrastructure system, the cultural framework and setting and the social system. These four sub-systems together constitute a larger complex system (Dammers et al., 2014). However, Voskamp et al. (2016) suggest in line with Haken (1983) that the complexity of urban systems (related to resources) should be described by integrating the quantitative knowledge of resource flows with the environmental, social and economic understanding. Research into complex systems is often divided in social-ecological systems and social-technical systems. Social-technical systems can be described as clusters of elements, like technologies, regulations, infrastructures, institutions, supply networks, markets, social practices and cultural meaning (Geels, 2005; Da Silva et al., 2012; Kern, 2012) that are constructed to be controlled (Pahl-Wostl, 2007) and that are highly institutionalized to realise societal functions (Smith et al., 2010). At the core of a social-technical approach is the interaction between technologies, material artefacts and human activity and actors (Mylan et al., 2016). Social-ecological systems can be described as human activities and associated water, energy and chemical fluxes (Ramaswami et al., 2012). Social-ecological systems aim at integrating ecological and social sciences to study coupled human and natural systems (Liu et al., 2007). Feedback and interaction between ecosystems and humans are key in social-ecological systems. A better understanding of the processes of human-environment interactions that affect the resource flows of cities is essential for sustainable resource management (Van Timmeren, 2006; Pahl-Wostl, 2007; Voskamp et al., 2016). Next to the suggested sub-systems in actual CE literature, concerning mainly social-technical sub-systems, incorporating social-ecological sub-systems as well, seems relevant.

An integrative CE evaluation framework for urban planning

Based on the vertical and horizontal integration, a V-H CE evaluation framework is suggested for urban planning, see figure 3. The framework aims for an integrative multi-scale, multi-disciplinary and systemic approach in which bottom-up and top-down efforts reinforce each other. This is in line with the suggestion by Voskamp et al. (2016) that for resource-conscious urban planning a multi-scale, systemic approach is needed to provide the required information on resource flows and the interlinkages between processes and resource flows.

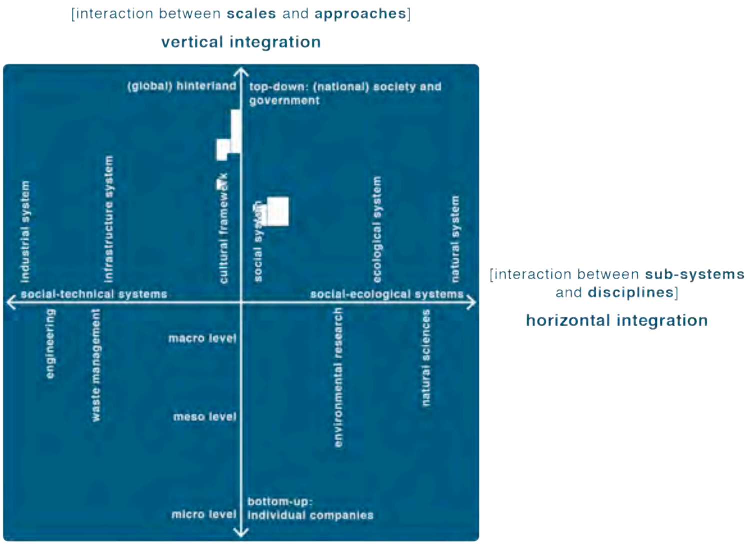

Figure 3: V-H CE evaluation framework for urban planning

CE urban planning document analysis of the Amsterdam Metropolitan Area

In order to understand how CE aiming strategies for urban planning are functioning in planning practice, four CE urban planning documents for the Amsterdam Metropolitan Area (AMA) and its surrounding region are evaluated according to the V-H CE evaluation framework. See figure 4. For vertical integration of scales focus was put on the arrow and for vertical integration of bottom-up or top-down approaches a triangle was used in the box of the document. Horizontally we focused on the interactions between sub-systems. The documents were analysed and key words found in relation to the vertical and horizontal integration in CE literature are used to determine the position in the evaluation framework.

From the analysis of the CE planning documents for the AMA and surrounding region it becomes apparent that the vertical integration of scales is often taken into account in the documents. At the same time, the integration with the (global) hinterland is often lacking in the documents. The vertical integration of top-down and bottom-up efforts is mentioned in two documents. The other documents focus on top-down efforts only. It can be concluded that vertical integration in CE planning documents for the AMA is partly taken into account. In the horizontal dimension however, less integration is taking place. Most of the documents have a social-technical focus and do not take the social-ecological systems or interactions into account. In document 02 and 03 some attention is devoted to ecological impacts. From figure 4 it becomes clear that the horizontal integration is not yet sufficiently embedded in current planning documents for a CE in the AMA and surrounding region.

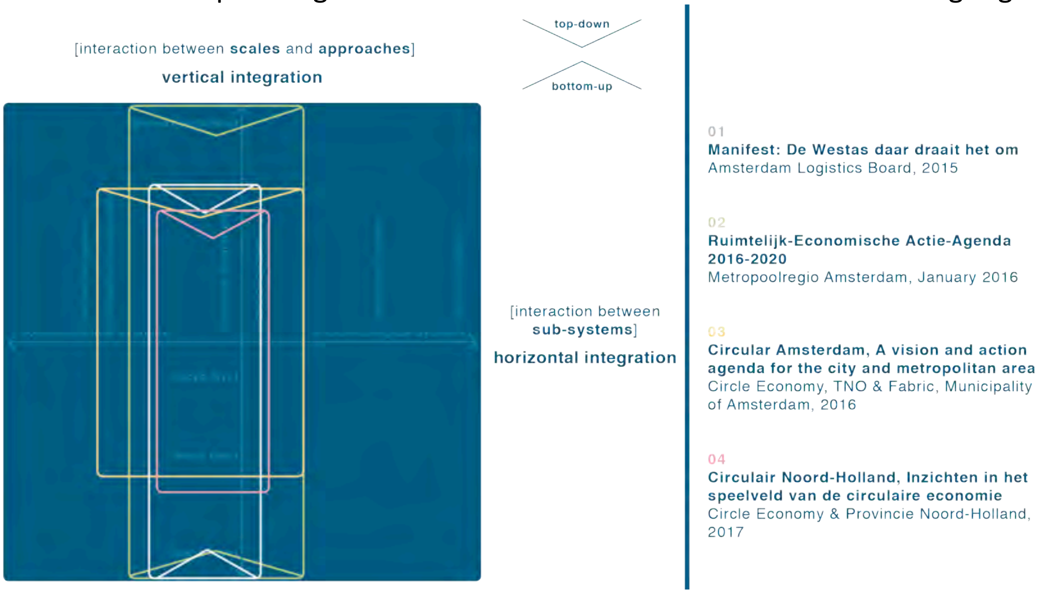

Figure 4: CE planning documents for the AMA in the V-H CE evaluation framework for urban planning

Discussion

There is a lack of horizontal integration of sub-systems in the AMA context, an presumably in other areas as well. A next step in the development of successful CE strategies in urban planning is that the current focus on social-technical systems of the planning documents related to CE for the AMA and surrounding region needs to be integrated with social-ecological principles. Wilkingson et al. (2013) show that a social-technical approach has been a traditional way to analyse urban complexity and that a social-ecological approach needs to be integrated. By combining and integrating a social-technical and a social-ecological approach a so-called SETS (social-ecological-technical-systems) approach can be achieved, in which social, ecological and technological aspects of environmental phenomena are considered leading to a better understanding, support and management of urban ecosystems (Ramaswami et al., 2012; Groffman et al., 2016). Ramaswami et al. (2012) point out that "complex, cross-scale interactions between the natural system, the transboundary engineered infrastructures, and the multiple social actors and institutions that govern these infrastructures" are necessary for the sustainability of city systems. The main challenge is the further development of this multidisciplinary approach, the integration of theories and methods of the engineering and design disciplines with the natural and social sciences (Groffman et al., 2016) and the implementation in the urban planning practice. Our current urban systems were built upon and exist within the paradigm of waste. There are many opportunities for investment into environmental technologies to achieve CE, such as cogeneration systems, biogas and anaerobic digesters for the purpose of harnessing essential flows of nutrients and recycling of clean water. Research into the feasibility and integration of CE for the built environment discovered numerous positive outcomes as long as systems are reciprocal and synergistic, building upon communities and the local natural environment. Or, differently stated, address both horizontal integration as well as vertical integration. While CE might not solve climate change and resource scarcity, it offers opportunities for planning and design of new and existing areas based on the principle of decentralized, interconnected, polycentric circular urban systems. Not only will urban planners need to re-examine traditional political and geographic boundaries, but the scalability of solutions, infrastructure, interrelated networks and the role of public space as well.

Further research is needed to investigate how the understanding of systems can be incorporated in urban planning and how a SETS (social-ecological-technical-systems) approach can be taken in urban planning for a CE. In such research, the development of methods to incorporate SETS and systemic approaches in urban planning of metropolitan areas is key.

Abstract: Economic development cannot be achieved without water. Water has helped drive modern-day economies through agriculture, industry, energy production and the maintenance of general quality of life. Currently, developing South-Asian economies like Pakistan are seeing burgeoning populations and rapid urbanization coupled with economic growth. Yet despite Pakistan becoming water deficient over a decade ago, policy and institutions surrounding water management remains fragmented and water is still considered a free good available in abundance. Resultantly, policy transitions emerging out of the socio-technical nature of water management and the need for integrative water resource management across different sectors has been slow. This paper describes output from an ongoing research project classifying actors according to roles, dependencies, influence and interests using qualitative and methods and Social Network Analysis. Grounded in the theory of networked governance and stakeholder theory, this paper presents the first part of the research findings, a situational analysis that explores the current state of affairs, constraints and enabling conditions for policy surrounding WRM in large urban centres of Punjab, Pakistan. Findings reveal that weak governance structure, poor capacity and lack of service focus have unfavourably impacted water aquafers as well as ground water utilization in Punjab. These conclusions have relevance for regional and local institutions as well as international funding bodies involved in the development of urban water infrastructure and policy in South-Asia.

Keywords: policy, water, actors, stakeholder interests, SDGs

Introduction

As developing countries continue to see rising middle class incomes and economic growth, household per capita water consumption is also on the rise (see Cosgrove and Rijsberman, 2014; Rijsberman, 2006) as well. Higher consumption patterns and burgeoning populations in developing countries also translate into higher demand of water for electricity generation, agricultural and livestock production as well as domestic and industrial consumption. This is leading to depletion of freshwater resources and ensuing water stress (Rijsberman, 2006).

Effective maintenance of water has been cited as one of the most significant factors contributing towards sustainability (e.g. in Schaffer and Vollmer, 2010) but while developed countries have been compelled to revisit their traditional methods of operations because of increasing environmental awareness, climate change, rising energy prices, population changes and the emergence of more complex regulatory frameworks (Marlow et al., 2010), the push factors in counties like Pakistan have been tempered with pragmatic constraints such as resource scarcity and an aging infrastructure that requires expensive replacement. Although the challenges faced in the first world are formidable, those faced by the developing world are arguably even greater, given that such countries have yet to reach the levels of socio-technical, managerial or regulatory sophistication that the developed world takes for granted. Urban centres in developing countries continue to struggle with what is called a 'brown agenda' i.e. issues pertaining to environmental health impacts- something the developed world overcame long ago- as opposed to what Allen et al. (2002) refer to as the 'green agenda' which the developed world now aims at. The situation is made worse by the fact that urban centres in developing countries are expected to continue to grapple with phenomenally high levels of urbanization and economic activity: both of which put pressure on water resources and service provision.

In Pakistan- a country battling with insurgency, terrorism and political instability- water scarcity is rarely highlighted as one of the most difficult issues challenging increasingly affluent, modern Pakistan. The country's growing, consumptive middle-class drives the hunger for production, energy and food- all directly or indirectly dependent on water. Pakistan's cities are urbanizing at a rate of 3% pa—the fastest in South Asia (Kotkin and Wendell Cox, 2013)[1]. However, cultural urbanization appears to be taking place in the country at a much faster pace than urbanization per se. Advances in information and technology, market development and exposure through media have altered rural locales into product-and-service-hungry 'virtual' cities (Iqbal, A, 2014). As access to water, electricity, natural gas and public services improves, rural lifestyles too are changing. This all leads to pressure over water- which is a primary input in food, energy, domestic and industrial production systems. These huge demands on water resources in the country are leading to groundwater depletion (at some places annual fall in aquafer level is almost 1 meter), turning rivers into wastewater streams and deteriorating water quality. Punjab (and Pakistan), however, are not alone in facing such a scenario. UN-Water's 'Water for a Sustainable World 2015' report (UN-Water, 2015) has identified poor groundwater maintenance, lack of institutional capacity and governance mechanisms as key causes of water problems in South Asia region.

Policy transitions in other developing countries have focused on different paradigm shifts. India and Indonesia have aimed for decentralization, and participatory governance, Turkey and Tanzania have transitioned to policy focusing liberalization of water services, while Thailand expects to move from all-year-all-year-around irrigation and farm-to-city water supply (Meijerink, S., 2009). Pakistan (and Punjab in particular) is aiming at sustainable groundwater management and improved service delivery. In lieu of this, several policy interventions have taken place over the last decade at the federal level as well as in Punjab, the most affluent province. Federal policies tend to trickle down into provincial policies, however Punjab has been progressive beyond the narrative provided by the federal government in terms of not only clear policy interventions but also improved service delivery through the establishment of independent water supply companies for rural supply.

Taking Punjab as a case study, this paper presents policy interventions in the water infrastructure sector and reports preliminary findings from a research project investigating the water sector dynamics in Punjab and classifying actors representing different levels of government and water sectors (e.g. urban water supply, industrial supply, rural supply, wastewater management and agriculture) integrate and ways in which this 'water network' supports or hinders current policy initiatives. The presents a situational analysis of practice in

[1] One can get a real sense of this unusual urbanization by considering the population of Karachi- the country's most industrialized port city- which grew by 80% in the decade ending 2010; the largest rise of any city in the world.

Punjab, that sets the base for primary data collection and analysis leading to the network governance framework (see Jones, C., Hesterly, W.S. & Borgatti, S.P., 1997).

Unsustainable Growth

The author's core argument behind presenting this situational analysis is that unsustainable development pathways being followed in Punjab, coupled with failures of local and regional government have put immense pressure on water resources in urban environments such as those on Punjab. This unregulated growth is beginning to effect water availability, quality and equitable distribution already despite most of Punjab benefitting from one of the largest underground freshwater aquafers in the world. The situation therefore compromises water's role in generating economic and social benefits for the region- an effect quite opposite to the one intended. Like most of the world's growth since the 1960s, economic growth in Punjab has also come at the cost of environmental and social degradation- aggravated by poor policy and governance mechanisms. A major hurdle in way of improving water service delivery in Punjab has basically been was the weak articulation of an urban sector vision and policy and an inherently inefficient structure of service provision (see World Bank, 2013).

The reason behind this has been the state's fixation on asset creation rather than the quality of services from those assets and demand-side management. Despite the relatively high levels of access to improved infrastructure in Punjab (such as filtration plants and pumping stations), the quality of access to services and an equitable distribution of services is poor and deplorably low. Like in many other developing countries, the thrust in has been on physical infrastructure rather than quality of services. Both the government and its development partners such as the Asian Development Bank and World Bank have put policy and reform on the back burner, while focusing on infrastructure upgradation almost entirely. There is therefore a need to promote a very different planning and policy paradigm: one that focuses on service, sustainability and value rather than asset creation through a fragmented developmental process. The need is to develop an urban sector vision that promotes an efficient structure of service provision.

Punjab (and Pakistan), however, are not alone in facing such a scenario. UN-Water's 'Water for a Sustainable World 2015' report (UN-Water, 2015) identifies poor groundwater maintenance, lack of institutional capacity and governance mechanisms as key causes of water problems in not only Asia-Pacific, but the Arab as well as Latin American regions. Recent international studies such as Zhang (2010) have shown the advantages of making urbanization work well and the firm role of effective planning and good governance in building thriving, productive, liveable cities.

Governance and Policy

Punjab's performance in most Millennium Development Goals (MDGs) indicators was far superior compared to other provinces. While the province either reached, or was close to achieving its annual targets for 2015, for most indicators, Punjab remained off track in achieving the targets (UNDP, 2015). Now that MDGs have run their tenure and are being followed by a wider-encompassing Sustainable Development Goals (SDGs), Punjab will need better policy and political will to meet the necessary targets, which it failed to meet with its MDGs. Water is targeted through multiple SDGs. SDG 1 (ending poverty) requires equitable distribution of freshwater. SDG2 indirectly includes water (sustainable agriculture). SDG 3 (well-being) requires clean drinking water provision for all. It is SDG 6 that explicitly puts water on the table: ensuring availability and sustainable management of water and sanitation for all. With targets set for 2030, Punjab must pull its act together and fast.

The government, conscious of the MDG situation, had launched a policy and institutional reform initiatives to address bottlenecks. In 2006, the Government of Punjab established an exclusive think tank to work in an advisory capacity on urban issues in Punjab. The “Urban Sector Planning Management Services Unit” (USPMSU) was given a mandate to respond to legal, institutional, technical and management needs of line departments and cities in Punjab. In 2008, the Government of Sindh replicated the Punjab model and established a “Directorate of Urban Policy and Strategic Planning”. In 2009, the Ministry of Environment ratified the “National Drinking Water Policy Framework” (World Bank, 2015). National Drinking Water Policy 2009 (Environment Department, Government of Pakistan, 2009) was followed by Punjab Drinking Water Policy 2011 (Government of Punjab, 2011) and the somewhat recent Punjab Municipal Water Act 2014 (Government of Punjab, 2014). While these are a step in the correct direction, the policies appear to have been created without the ground realities of Punjab’s complex situation in mind. This is where the fault lies.

To understand the current practice of water ‘management’ in urban centres of Punjab, one needs to visit the Punjab Local Government Ordinance 2001 (PLGO 2001) which was promulgated to devolve political power and to decentralize administrative control within the Punjab province. The Ordinance placed the responsibility for the provision of water supply and sewerage services with the Tehsil Municipal Administrations (TMAs) - a ‘Tehsil’ being a sub-district level administrative unit in Punjab. However, the ordinance did not place the burden of financing these services onto local governments.

A myriad of stakeholders and governmental agencies are part of the water landscape in Punjab’s urban centres. Most important being the Government of Punjab, represented by the Planning and Development Department, Housing Urban Development and Public Health Engineering Department (HUD&PHE), Development Authorities, TMA, WASAs; TMA staff as government employees, elected local government officials (Tehsil Nazims), council members, household customers, non-served households as well as commercial and industrial customers (although the share of industrial enterprises being served by public water supply is small), international financing agencies such as World Bank and Asian Development Bank, consumer groups and unions.

While TMAs remain administratively responsible for services such as water, sewerage and solid waste, it usually hands over the mandate to existing bodies such as waste management companies and Water and Sanitation Agencies (WASAs). Institutional mandate of service providers in large cities of Punjab is such that water and sewerage, drainage and solid waste. Functions are executed by three separate institutions within the city. In some cities like Lahore, Multan and Faisalabad independent solid waste companies have been formed. These companies collect, transport and dump solid waste in an organized way, usually to less detriment to water bodies (surface water) and aquafers (ground water). In other cities, however, solid waste is usually the function of a Solid Waste Directorate where its sweepers keep streets clean by dumping waste into drains. These drains are managed by the Town Municipal Administration (TMA). The TMA staff, given inadequate solid waste disposal facilities like landfill, sometimes keeps drains functional by pushing solid waste into sewers, which are the responsibility of WASAs (World Bank, 2015). Large open urban drains called “Nallahs” usually feed this untreated waste water into rivers or other water bodies leading to surface water contamination. These water bodies are, in turn, the responsibility of the Punjab Irrigation Department. Administrative stakeholders, therefor, are sometimes at loggerheads with each other, sometimes with roles overlapping e.g. the TMAs and local government provides the funds and sets the tariffs of services, whose delivery they have little or no control over. Authority and coverage is also ambiguous in areas whether the definition of ‘urban’ and ‘rural’ is unclear. This has led to certain areas of cities left without service (like solid waste collection and drinking water provision) altogether.

Apart from Lahore, Punjab’s other large eight cities i.e. Faisalabad, Gujranwala, Multan, Rawalpindi, Bahawalpur, Dera Ghazi Khan, Sargodha and Sialkot were studied by a German consultant in 2006. The findings, while interesting for outsiders, merely confirmed what insiders and practitioners had known all along. The report debated over issues of urban service delivery institutions and structures, legal provisions, reforms, inter- and intra-institutional alignment at the provincial and city levels as well as institutional and governance framework of urban service delivery institutions (data is usually not readily available and dependable, publicly-available reports have been few and far between. Fitchener, 2006 is a good example). Two of the most important findings were:

- The service providers are horizontally and vertically integrated organizations i.e. they are responsible for a particular service like water, sewerage and sanitation (horizontally integrated) and also vertically integrated from source to consumer and from consumer to final point of disposal. This gives them a wider prevue of each city’s needs;
- Non-Revenue Water (NRW) was identified as the priority area in the Punjab utilities by the five WASAs of Punjab (World Bank, 2015). The data collected from the WASAs on NRW revealed that WASAs were losing PKR 2.5 billion/year because the electricity bill for pumping water which was unbilled. The willingness-to-pay (WTP) and social surveys conducted by Government of Punjab showed end-users as generally unsatisfied with the quality of water and sanitation services, hence the reluctance to pay their bills.

Apart from the above, some key gaps identified by various reports over time (WAPDA, 2003; FODP, 2012) in the legal system surrounding urban water include a dearth of drinking water quality standards, monitoring and enforcement procedures; tariff making rules and guidelines; an unclear allocation of responsibilities; a dearth of effective performance monitoring mechanisms, blurred asset ownership and poor asset inventory keeping; and non-existence of effluent standards and water resource protection (including abstraction permits and control).

Table 1: Punjab Water and Sanitation Agencies Data

Description	**Unit**	**Faisalabad**	**Gujranwala**	**Lahore**	**Multan**	**Rawalpindi**
Population	million	3.1	1.7	6.2	1.8	1.3

Source: WASAs and TMAs

The coverage of various water and sanitation agencies in Punjab can be seen in the Table below. It is worth noting that apart from Lahore, there are practically no metered connections in the other large eight cities of Punjab. Consumer connections are not metered and payments are made on a variety of scales. Some relate to property area, others to the size of the pipe supplying to the property. Illegal connections are widespread while service providers have limited powers and resources to tackle the problem effectively (see Fitchener, 2006).

Current Practice

Punjab benefits from one of the largest aquafers in the world as well as historically sufficient surface water through three rivers Chenab, Jhelum and Indus. The name '*Punj-aab*" itself means the land of five rivers. Historically the province profited from supplies from five rivers, two of which were later conceded to India through the transboundary Indus River Basin Treaty in the 1960s. Given this good fortune, Punjab has remained the most prosperous province of the country contributing to over 58% of the country's GDP, both through agriculture as well as industry.

However, with population growth, urbanization and a huge agricultural sector which utilizes irrigation water inefficiently, Punjab is now below the Falkenmark Water Stress Index. The Index's threshold value is 1000m3/capita/year. While Pakistan's overall Index is 1200m3, Punjab's has fallen to 910m3. Total water availability (surface and groundwater) is expected to come under further stress with the index expected to fall to 770m3 by 2025 (source: Punjab Irrigation Department). As meagre amounts of additional water can be expected in the system at any point in time, the situation is dire.

Punjab specifically and Pakistan in general is as high-risk area due to climate change. While glacial melting in the Himalayas due to global warming is expected to increase water in rivers over the next 50 years or so, this will lead to eventual reduction in flows. There is already an increased variation in rainfall patterns, with larger dry spells (such as those between years 2000-2007), and increased flooding and drought situations. It is expected that by 2070, surface water may see declines of 30-40%. While these scenarios need to be studied more scientifically, existing data does paint a grim picture for water-dependent Punjab. The province has also seen a continuous degradation of surface water and groundwater due to dumping, pollution, seepage, use of fertilizers in agriculture and untreated affluent disposal by industrial units. Water quality has especially degraded close to urban centres, which house half of Punjab's population. The level of degradation is so high that natural ecosystems do not have enough time to regenerate and provide ecosystem services historically provided.

Groundwater from the Indus aquafer has also been exploited excessively. According to the Department of Irrigation, one Million Acre Foot (MAF) of water was extracted in 1965. Since rainwater runoff allowed for a recharge of 43 MAF annually, a program was laid out to extract this amount through tube wells. This supplementary source of water was found extremely useful by farmers and the trend grew. Although public tube well development declined after the 1970s, private (unregulated) tube well development flourished. In 2000-1, there were 0.6 million private tube wells in Punjab. Water Sector Capacity Building and Advisory Services Project (WCAP) of the World Bank estimated the number to be 1.1 million in 2008-9. Because water extraction is unregulated, the amount of water extracted is also a guesstimate. However, there is a rapid lowering of the water table in the aquafer, especially around urban centres such as Lahore, which have been deemed critical. The Punjab Irrigation Department, which monitors groundwater levels estimates that the water table is being lowered by more than one foot a year in the Bari Doab areas.

On the city-level, water and related assets are owned by local governments. Although the Local Government and Community Development (LGCD) department may be construed to be the caretaker department for the assets. Assets are not registered, not their functionality and replacement monitored. In fact, most are not formally assigned to city governments for monitoring and control. No asset inventories or registers exist, neither are there comprehensive maps showing their location, date of construction, materials or current condition and serviceability. Information regarding assets is generally scant. There also seems to be no financial record-keeping for amortization and replacement purposes.

Fitchener (2006) found that water assets in Punjab were severely aging and that there were heavy limitations on operation and maintenance expenditures. Numerous assets, the study concluded, were in poor condition and are usually fully depreciated already or operating at minimal capacity due to age and wear and tear. The situation continues to date whereby outdated, depreciated assets continue to operate in a financially constrained environment. Due to the poor shape of assets, water losses from pipes, is estimated to be almost 60% of the supply in some cities (Fitchener, 2006). Typical water supply assets are deep-cased and screened tube wells fitted with turbines or pumps. These tube wells are frequently located within the vicinity of the area to be serviced. Water is extracted from the ground and distributed through groundwater pipes to end-users. There is no measurement of the volume of water extracted nor are consumers charged with the cost of extraction.

Not surprisingly, the problems faced are not only about extraction, assets or technology. The availability of the requisite technical and managerial skill set is also an issue. This is because of traditional human resource (HR) practices in the public sector. Performance, for example, does not have much influence on career advancement, thereby limiting the need for innovation or higher performance by staff. Also, recruitment bans are the norm, and staff planning and capacity building is unheard of. Commercial and customer service skills are neither developed not considered important. In fact, several water agencies struggle with technical staff numbers and capabilities such as operational skills as well. According to the Fitchener Report (2006), formal standards for service do not exist currently. Although variations between cities can be expected, quality is generally poor, with water agencies totally lacking the service mind-set.

Conclusions, Policy Options and Priorities

The situational analysis presented in the paper shows Pakistan's current practice to be manifestly unsustainable. Although reform is not a new concept and we have a series of policy initiatives taking place in Punjab in the form of policies and acts, the need for a much wider, more holistic reform is as urgent as the severity of water challenges constraining the country's growth potential and the liability of its cities. Other Asian cities that can proactively re-positioning themselves as live-able, economically viable and sustainable cities will be those that will plan and manage water resources in a more holistic and long-term way. It is these cities that will attract investors and stay healthy abodes for populations. Cities in Punjab must compete with these cities. To do so, several areas became apparent from the interviews conducted with several state actors including the addressing the poor state assets, improved service quality, policy adoption in practice, wider water and Environmental Management: better accountability, monetization of water and a far more robust regulatory environment.

Much of these proposed actions may be initiated in the short-term. However, large scale capacity building or the development of new, technically sound bodies to replace existing bodies would have to be undertaken. I concede that radically progressive, well-functioning planning and executing systems may not be possible immediately. Local governments differ from one city to another. However, given the severity and scale of the problem, action must be initiated somewhere. Private sector involvement for financing and best practice must not be ruled out. As policymakers work to renew the existing water management paradigms in the developing world, they need to recognize that water planning is one the most fundamental and important issue pertaining to their populations: one far more important that physical transport infrastructure (as has been the onus in Punjab). The prevalent system is not close to being prepared to support the country's economic growth. Punjab's lack of planning for water risks is aggravating unsustainable development, a declining quality of life and is ultimately undermining the economy.

Aquaponic as a System of Building Integrated Food Production

Friederike Well[1]

[1] Technical University of Munich, Munich, Germany, friederike.well@posteo.de

Abstract: This paper describes the planning parameters to integrate an aquaponic system into a plus-energy house in Austin/Texas. The idea behind this is to close material cycles in the sense of Cradle to Cradle® and to consider existing waste as resources. Therefore, it was examined whether condensation water generated in air conditioning systems (fan coils) can be used to produce food in an aquaponic system. Aquaponics is a technology that combines fish farming and crop cultivation in a circulatory system. In this project, a new aquaponics concept of the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) is used, which provides individual water circuits for fish and plants, to allow the optimal conditions for fish farming and plant cultivation. The system is placed in a greenhouse. Tilapia were selected as suitable fish. Tomatoes and other crops grow in a “medium based” bed of 3,5 m^2 with a substrate of coconut fibre mats. Thus, about 75 kg of fish and 50 kg of vegetables are produced per year directly at the consumer's place of residence and in a nature-like circulation system.

Keywords: Aquaponic, Sustainable Building, Greenhouse, Water reuse.

Introduction

The impact of climate change calls for special protection of resources on Earth. Water is a particularly valuable resource, as it is the basis of life for man and nature. Reducing water consumption should therefore be targeted. An average American has a daily water consumption of 101.5 gallons (384 litres) in the household. Most of this is used for personal care. Approximately 70% of the water consumption takes place in interior spaces. 30% are used on the garden and outside (City of Philadelphia, 2017). In addition to this direct water consumption, the water footprint also shows the indirect (also known as virtual) water consumption caused by the production and transport of goods. This is where the USA has world’s largest. An average American citizen has an indirect water consumption of 2480 m^3 per year. This corresponds to 6,800 litres per day. In comparison, China has an average water footprint of 700 m^3 per capita per year (Hoekstra and Chapagain, 2006).

An integrated aquaponic system offers the possibility to reduce both, direct and indirect water consumption. The use of recycled water avoids additional water consumption from the public drinking water supply. The hydroponical cultivation method is twice as efficient in water consumption than conventional vegetable growing in the garden (Kloas et al., 2015). Furthermore, the water footprint of the inhabitants is reduced because the need for fresh food can partly be covered by self-cultivation. The world-wide average for 1 kg of tomatoes is 214 litres of virtual water (Matzke-Hajek and Vereinigung Deutscher Gewässerschutz, 2011). This consumption can be reduced by local cultivation and the use of recycled waste water.

NexusHaus

The NexusHaus was developed as a contribution to the international competition "Solar Decathlon 2015" by a team of the University of Texas at Austin and the Technical University Munich. It was planned and modified for three locations: Austin/Texas, Irvine/California and Munich/Germany. This paper focuses on the location in Texas. The aim was to create a plus energy house based on three principles according to the Cradle to Cradle® philosophy: Waste equals food, use current solar income and celebrate diversity (Salfner et al., 2017). The sustainable use of water was a key element in the planning process. The building is based on a modular concept, which can be enlarged for households with many people. In this work, the basic variant of the NexusHaus, which consists of two building parts, a day and a night module, with a connecting terrace, is adapted (Fig. 1).

Figure 1. NexusHaus Floor Plan.

Aquaponics

Aquaponics is a technology for food production, which makes use of the symbiosis of natural material cycles. It combines recirculating aquaculture (fish production) with hydroponics (plant cultivation without soil) by nitrification. The excrements of the fish (ammonium and ammonia) must be removed from the water. Like it is shown in Fig. 2 aquaponics converts these substances by means of bacteria into nitrates, which are then used as plant fertilizers. By absorbing the nutrients, the water is filtered and can be returned to the fish (Blidariu and Grozea, 2011).

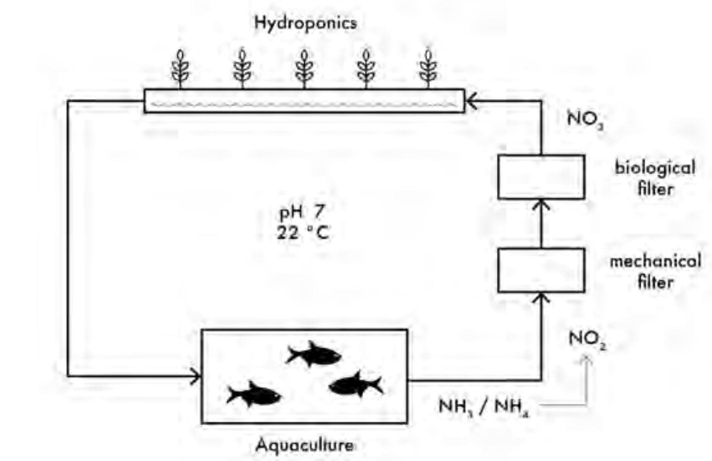

Figure 2. Function of a single circuit aquaponic system.

Aquaponics considerably reduces the water consumption for fish production and plant cultivation. In the research project ASTAF-PRO, 1 kg of fish (tilapia) and 1.67 kg of tomatoes were produced on average with 220.6 litres of fresh water in a testing period of nine months. Compared to a conventional recirculating aquaculture this requires less than ⅓ of the water consumption (Kloas et al., 2015). ASTAF-PRO employed a special technique in which the aquaculture and hydroponics circuits were decoupled and the water quality was regulated separately for plants and fish. (Fig. 3). As a result, both systems could be optimized to meet their needs in particular with respect to the pH value.

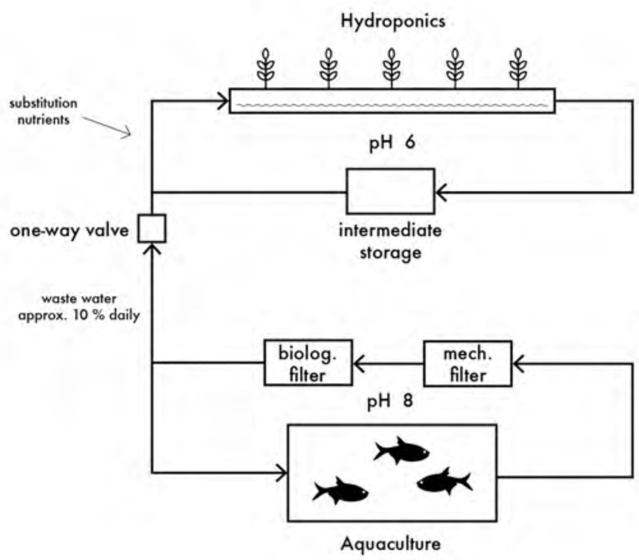

Figure 3. Function of a decoupled aquaponic system.

Since aquaponics works independently of soil conditions and can be adapted to many climatic conditions, it plays an increasing role in the question of food security and food production in water-poor areas. In 2012 the Food and Agriculture Organization of the United Nations (FAO) supported 15 families in the Gaza Strip with small aquaponics units to enable them to produce food independently in backyards and on rooftops (Somerville and Ferrand, 2013). A third project, which is referred to is the aquaponics facility of the “Arche Noah” in Menden, Germany. It is a medium-sized project that has been designed to be particularly energy-efficient in middle latitudes. The three systems are compared in Table 1.

Materials and Methods

To determine the integration of an aquaponic system into a single-family home, several aquaponic systems were first analysed and tested for compatibility (Table 1). The projects showed marked differences in their objectives. The ASTAF-PRO project at the IGB Berlin (also known as "tomato fish") is, for example, a research project that focuses on a larger scale for industrial production. Therefore, a profitable workflow is an important goal.

Table 1. Comparison of listed aquaponic systems

Name and location of aquaponics	Type of system	Size of the fish tank / growing area	Hydroponic system	Type of fish	Type of plants
ASTAF-PRO, Berlin	Decoupled	10 m^3/ 116 tomato plants	NFT (nutrient film technique)	Tilapia	Tomatoes
FAO, Gaza	Single circuit	1 m^3/ 4 m^2	Media based (volcanic gravel)	Tilapia	Mixed
Arche Noah, Menden	Single circuit	2 m^3/ 2 m^2	Media based (gravel)	Tilapia/ carp	Mixed

The FAO project focuses on autonomous food supply in politically troubled areas. Although a small scale is foreseen, the aquaponic system has been designed for other climatic conditions and is, therefore, only to a limited extent comparable to the NexusHaus. Also, the aquaponic project of the “Arche Noah” in Menden has a small scale. However, the focus is on teaching children in context of environmental education. Another goal is sustainability and energy-efficient operation.

Based on an analysis of the presented systems, key parameters for an aquaponic system, which can be integrated into the NexusHaus, have been defined: Use of recycled water as resource so that no additional consumption of fresh water from the public utility network is needed. Energy-efficient operation throughout the year and a user-friendly handling and care, that doesn’t require expert knowledge.

Water

The aquaponic system is to be supplied exclusively with water, which is produced in the house as a "waste product". The first consideration was to use the condensation of the fan coils. To determine the suitability of this option, the water quantity must first be determined. It is known that when cooling, the interior air forms condensation water because warmer air can absorb more moisture than cold air. For this reason, air conditioning systems have a line to the sewage system of the building. However, the respective amount of condensed water is dependent on numerous components like absolute humidity, relative humidity and air temperatures. In case of the fan coils, only the interior air is cooled and there is no fresh air supply (Daniels, 1996). For this reason, the accumulating humidity only results from the perspiration of the bodies of the inhabitants and their activities in the house.

It is assumed that a person exhales an average of 50 - 150 g of water per hour depending on their activity. In addition, moisture is released to the air when showering, cooking and drying. Therefore, according to a rough estimate it is assumed that three litres of moisture are released to the interior air per inhabitant daily (Baunetz Wissen, 2017). This value, however, fluctuates strongly and is in a great extent dependent on the presence of the inhabitants.

The quality of the condensed water is suitable for aquaponics. The pH is in the neutral range, which corresponds to the requirements. In addition, the pH in the system must be checked and adjusted again and again, to not harm the fish. Although the condensed water of the fan coils can be used in aquaponics, this option is not recommended. The reasons for this are mainly the high effort compared to a very strongly fluctuating and rather low gain. Since the required amount of condensation water cannot be guaranteed with certainty, but an aquaponic system needs fresh water every day, two other options for water extraction from existing resources (rainwater and greywater) will be examined in more detail below.

For the NexusHaus it is planned to catch the rainwater. However, the water thus obtained is intended for the thermal storage tank and is therefore not available for aquaponics (Salfner et al., 2017). In principle, rainwater is very suitable for aquaponics. The EU-funded research project INAPRO, developed based on ASTAF-PRO, aims to cover the fresh water demand completely through the collection of rainwater (Kloas et al., 2015).

The third possibility is the use of greywater. In the NexusHaus the domestic separation of blackwater and greywater is planned. Greywater is waste water from the shower, the bathroom sink and the washing machine that is free from faeces. On average about 163 litres can be collected daily, which are not directed into the public sewage system, but are treated directly in the house for reuse (Salfner et al., 2017). If the demand for toilet flushing and washing machine are removed, a daily average of 120 litres remains, which could be utilised to the aquaponics. In this case as well, the water quality must be monitored and adjusted if necessary.

An aquaponic facility needs about 10% of the water volume of fresh water every day. This value can be reduced even further with well-balanced and monitored system. ASTAF-PRO provides, for example, 3-5% water requirement per day (Kloas et al., 2015). When using recycled greywater, the required amount of water would be reliably available and it would also be possible to tide over several days if the inhabitants were not present.

Location

For an integration of aquaponics into the NexusHaus, it must be decided where the system is to be placed on the site. Various possibilities are conceivable. A placement within the thermal envelope has the advantage of constant temperatures. Nevertheless, this option is discarded because the humidity should be higher for plant cultivation than it is in most dwellings and fish odours of aquaculture could disturb the well-being of the inhabitants. In addition, there is a greater need for artificial lighting to ensure good plant growth and the housing space of the NexusHaus has been narrowly dimensioned.

An open-air planting is also feasible. In this case, however, control of the temperatures becomes more difficult. In addition, the rain shelter of a greenhouse counteracts a pest infestation (tomato late blight) (Meyer-Rebentisch, 2017).

After weighing up these aspects, the decision was made to stay on the south side of the day module, as originally planned in the NexusHaus (Fig. 1). In contrast to the competition design, the system is placed in a greenhouse, which also houses the fish tank. In the combined placement of fish and plants, a favourable metabolism takes place. The plants convert the CO_2 released by the fish into oxygen (Kloas et al., 2015). The area between the ramp and the house wall offers enough space for a small aquaponic unit on an area of about 6 m².

Fish

The selection of suitable fish for aquaculture should be made regarding regional conditions. The corresponding comparison factors of three fish species are listed in Table 2. Tilapia are particularly suitable due to their uncomplicated housing conditions and have proved themselves as "standard fish" for aquaponics. However, other species are also possible. In Central Europe, where temperatures are lower than in Texas, carp and trout would be an option. The carp, because it is very resistant even at cold temperatures. The trout, because it is a very popular food fish. Trout is excluded because it gets along very badly with water temperatures above 20 ° C (Würtz, 2017). According to the food preferences in the US, the African catfish is considered as an option for the location in Austin/Texas.

Table 2. Different fish species for aquaponics

	Nile tilapia *(Orechromis niloticus)*	Common carp *(Cyprinus carpio)*	African catfish *(Clarias gariepinus)*
Temperatures	14-36 °C (optimal 27-30 °C)	4-34 °C (optimal 25-30 °C)	5-34 °C (optimal 24-30 °C)
Stocking density	60-150 kg/m³	10 kg/m³	max. 350 kg/m³
Oxygen content	With oxygen supply higher feed conversion ratio	No supply necessary	Tolerates little oxygen
Consumption	Versatile food fish	Many bones, very fat, only moderately popular	Versatile, very popular in America

For the NexusHaus tilapia are selected as suitable aquaculture fish. Due to the low demands regarding the housing conditions, their tolerance to high water temperatures, which are to be expected in the summer and the proven suitability for aquaponics, they are most likely to be used for year-round operation. If favoured by the inhabitants, carp or catfish can be used as an alternative. For these two species, there is less quantified experience in aquaponics, though.

Plants

For the inhabitants of the NexusHaus, the handling and the use are particularly important in the selection of the plants. For this reason, a "media-based bed" should be chosen, in which different plants can be cultivated. The substrate used are coconut fiber mats, which must be exchanged more frequently than mineral substrates, but are compostable in the sense of Cradle to Cradle® (Somerville et al., 2014). It would be ideal to find a regionally available organic raw material, which can serve as a substrate.

For the planting mainly tomatoes are used, as well as herbs and lettuce. With these plants, the design and calculation of the aquaponic system is made. However, plants can be replaced at pleasure (for example, cucumber and pepper instead of some tomato plants).

Results

In order to achieve higher yields and improve the stability of the system, the decision was based on a two-circuit system. The first circuit contains a recirculating aquaculture with tilapia and is connected via a one-way valve to the second circuit, which contains hydroponics. The entire system is housed in a greenhouse that can be shaded and additionally has air conditioning to compensate for the high temperatures that prevail during the summer months in Texas.

The fish tank holds a volume of 500 liters. It contains 35 kg of fish which is graded in different sizes. Large fish are regularly removed and smaller ones are added so that the stocking density is always in the ideal range of 60-150 kg / m³. Figure 4 shows the arrangement of the aquaponic elements. Above the fish tanks are the beds located. The waste water from the fish tank is cleaned from solids in the mechanical filter and nitrated in the biological filter. The water then flows through the one-way valve into the sump, where missing nutrients are added and pH is adjusted. The water is pumped to the beds where strong starters like tomatoes, peppers and cucumbers are grown. Lettuce and herbs can always be added in the beds because they are less nutrient-needy.

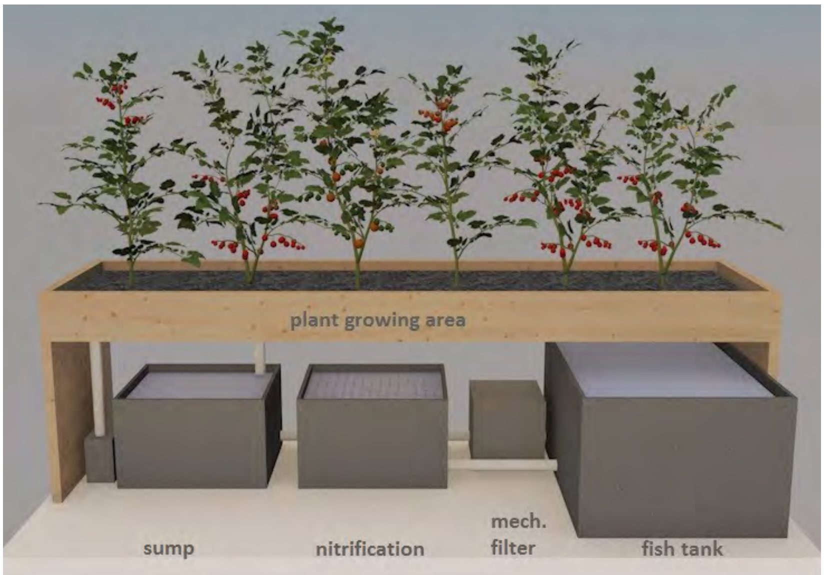

Figure 4. Design of the NexusHaus aquaponic unit.

The fish tank is insulated to compensate for large temperature fluctuations. In winter, night temperatures in Texas can approach the freezing point, which is why a heat exchanger is installed for heating and cooling. It is connected to the thermal storage of the house. The presented aquaponic produces about 75 kg fish per year and 50 kg of tomatoes or other vegetables in a growing season of eight months.

Discussion

When integrating an aquaponic system into a single-family house, it must be clarified whether the system can still be assessed as "sustainable". It is remarkable that a high energy expenditure is necessary in order to keep all parameters in equilibrium. For example, heating energy must be applied in winter and cooling energy in summer. In addition, investment costs are relatively high for a small plant. In the case of a larger installation, these critical points are significantly reduced. However, if it is possible to cover the energy expenditure from self-generated renewable energies and the investment costs are taken into account, the question arises as to how the system is pleasant to use for its users. Basically, aquaponics is only to be used after thorough instruction. A good understanding of fish farming and plant rearing is important to avoid mistakes. The system requires a lot of maintenance. Despite feeding equipment and automated operation, a daily inspection is urgently recommended. The quality of water must be checked regularly, which in the ideal case could be transmitted via sondes that send digital readings to the residents' smartphone.

The presented results could not be practically tested. This would be necessary, in particular, to determine the climatic conditions in the small greenhouse more precisely, thereby quantifying the energy expenditure.

Conclusions

It is possible to integrate an aquaponic system into the NexusHaus and to reuse water that is generated as a waste product. The fresh water supply with treated greywater is favored because the required amount is constantly available. The system is to be housed in a greenhouse on the south side of the day module. It contains a 500 litre tank, which is used to cultivate tilapia with 35 kg biomass all year round. The hydroponic plant cultivation is to take place from April to October in a media-based grow bed in which coconut fiber matts serve as substrate. A heat pump to the thermal storage of the NexusHaus keeps the temperature in the fish tank constant. The yields of 75 kg of fish and 50 kg of tomatoes per year would lower the needs of the residents for external food supplies and thus have a positive impact on the water footprint.

Potential cooling energy reduction by a wind tower model in Milan and Rome climate

Mehrnoosh Ahmadi[1] and Mario Grosso[1]

[1] Department of Architecture and Design, Polytechnic University of Turin, Turin, Italy.

Abstract: The human-induced emission of greenhouse gasses has largely contributed in the current quickly proceeding earth warming. The building sector represents 19% of all global GHG emissions and one-third of CO2 release, most of which are indirectly coming from the electricity consumption in buildings. The inevitable increase of cooling energy demand due to global warming, improving life standards and population growth associates with a higher electricity consumption and more CO2 emission. Therefore, implementation of passive ventilation and cooling strategies as an alternative solution for providing human comfort becomes of vital importance in saving of building energy and hence contributes in climate change mitigation set by United Nations Environment Programme (UNEP). One of the ventilative cooling components that despite its antiquity has only lately attracted attention of sustainable designers and engineers is the Iranian wind tower. A previous parametrical analysis of a wind tower model using SPERAVent—a simplified thermal simulation tool for calculating the potential cooling energy reduction due to controlled natural ventilation—showed promising results in Palermo climate conditions. In this paper, a similar assessment has been done using Milan and Rome weather data and the possible application of wind towers in different climatic zones has been investigated.

Keywords: ventilative cooling, wind tower, SPERAVent, cooling energy reduction, controlled natural ventilation

Introduction

Statistics show that from 32.4 PWh final energy used in the world in 2010, 32% was in the building sector (24% in residential and 8% in commercial) (Lucon et al, 2014). IEA suggests that the energy use in this sector continues to grow at an average rate of 1% per year with households accounting for about 60% of the increase in energy demand, majorly in form of electricity (IEA, 2013). Furthermore, in the same year, the building sector's emissions of greenhouse gases (GHG) represented 19% of all global GHG emissions and about one-third of the CO_2 emissions, indirectly coming from the electricity consumption (Lucon et al, 2014). In fact, the associated indirect CO_2 emissions, at 5.6 Gt, are almost twice as large as the direct emissions in the buildings sector itself (IEA, 2016). Inevitably, part of the climate change mitigation policies set by United Nations Environment Programme (UNEP) is to impose new or higher energy performance standards in buildings for lighting, heating and cooling appliances (IEA, 2013).

Space cooling currently accounts for an estimated 5% of total final energy consumption in buildings and as the ETP models estimates, it is the fastest growing end use in this sector (IEA EGRD, 2016) partly due to global warming and further because of the improving life standards and cost-effectiveness of air-conditioning appliances for increasing number of population (Kamal, 2012). In fact, IPCC estimates that the global demand for residential air conditioning alone will rise from 300 TWh per year in the year 2000 to 4.000 TWh in 2050 and 10.000 TWh by 2100, with the majority of growth in developing countries. About 75% of this increase is due to rise of income in emerging market countries and 25% is due to climate change (Arent et al, 2014).

Among all technological options for reducing cooling demand, ventilative cooling represents an attractive energy efficient passive solution for cooling and overheating prevention (IEA EGRD, 2016). One of the ventilative cooling components that has attracted the attention of sustainable designers and engineers is the antique Iranian wind tower a.k.a. Badgir which was commonly employed in traditional climatic architecture of desert cities of Iran. In hot arid regions of Middle East, where cities were formed compactly to hinder sand storms and excessive sunshine from reaching a human level (Ghobadian, 2008), wind towers were constructed in order to convey the cooler, fresher and cleaner wind of a higher altitude into the buildings. Also, their role in maintaining a constant airflow in public cisterns was crucial in preventing any dew or humidity from forming inside the cistern (Memarian, 1993).

Literature review

Wind towers perform under two conditions. When there is wind, the distribution of positive and negative pressure coefficients around various mouths of wind tower and other building apertures will create an airflow from the positive pressure openings to the negative ones. Instead, when there is no wind, often at night, the solar radiation heat, stored in the tower during the day, releases into the tower and creates a stack effect which results in an airflow into the buildings through the windows (Bahadori et al, 2014).

A CFD analysis of a model _a room and a commercial wind tower on roof top_ compares the effect of wind and buoyancy. In case the ventilation only relies on the tower and there is no other opening in the room, the airflow is mainly wind-driven and the buoyancy effect is negligible. Instead, adding a window on the leeward side of the room will provide 47% more airflow (Hughes et al, 2011).

Other studies focusing on geometrical elements of the wind tower show how the height of the tower, its section shape and measurements and its internal divisions can affect the temperature and mass flowrate of the air entering the building (Bahadori et al, 2014).

CFD and wind tunnel test with smoke visualisation show that increasing the number of openings of the tower decreases its sensitivity against wind angle, while the natural ventilation performance of those with fewer openings drops more considerably when the wind angle increases (Montazeri, 2010).

Another CFD analysis shows how a rectangular wind tower has a better efficiency than a cylindrical one due to its sharp edges that create a greater flow separation and higher pressure differences across the tower (Elmualim et al, 2002).

A smoke visualisation test proves that in one-sided wind towers, for an approaching air velocity of 10 m/s, inclined- and curved-roof towers have 7% and 15% more entering flow rate respectively (Kazemi et al, 2012).

Assessment of potential cooling energy reduction by a wind tower model using SPERAVent

SPERAVent is a simplified dynamic thermal simulation tool for evaluating the hourly energy behaviour of a building consisting of no more than two thermal zones, during the cooling period (Grosso et al, 2011). This program has been utilised previously for a parametrical analysis of a conceptual model comprising a one-channel wind tower and a room in Southern Italy –Palermo– climate and has shown a saving of between 43% and 61% in annual cooling demand (Grosso et al, 2016). In this paper, the same model has been assessed considering Milan and Rome climatic conditions.

Climate of Rome and Milan

The climatic characteristics of Milan and Rome are summarized in the following table (windfinder.com, n.d.) (climatemps.com, n.d.).

Table 1. Comparison between Milan and Rome climatic conditions.

Milan	Rome
45°26'N, 9°16'E, 103 m	41°57'N, 12°30'E, 24 m
Humid subtropical climate (Köppen-Geiger classification: Cfa)	Hot Mediterranean, subtropical climate (Köppen-Geiger classification: Csa)
The annual average temperature is 12.5 °C	The annual average temperature is 15.1 °C
The warmest month is July with mean temperature of 23.1 °C	The warmest month is July with mean temperature of 23.95 °C
The coolest month is January with mean temperature of 1.35 °C	The coolest month is January with mean temperature of 7 °C
Average annual precipitation is 943.2 mm	Average annual precipitation is 837.3 mm
Annual wind direction distribution (%) 	Annual wind direction distribution (%) 
The model characteristics

The model (Figure 1) chosen for the assessment comprises of a one-story square room with an area of 25 m^2 and a height of 3 meters and an 8-meter high wind tower with a square cross section and a surface area of 2.25 m^2 which makes the volume of the whole model 91.875 m^3.

The specific thermal capacity of room and tower is rather close as the finishing materials for both calculated units are similar. Mortar is selected for external finishing, plaster for internal one and wood for the flooring. The thermal bridge is thought to have a 5% adverse effect in dispersion of energy between internal and external environment. As part of this assumption, walls are supposed to have exterior insulation coating without any overhangs or balconies.

In the first set of assessments (orientation effect), all the opaque surfaces including walls, ceilings and floors, of both room and wind tower are thought to be identical as a matter of thermal energy transmittance. They are all considered medium weight with no/external insulation having rough light-colour surfaces. Therefore, their heat capacity is 155 kJ/m^2K and their thermal transmittance is 0.3 W/m^2K. In the second assessment, the effect of different heat capacities of opaque surfaces on cooling energy reduction has been studied.

The tower has openings on all four sides, one of which is alternatively opened during the simulation. Similarly, the room has windows on three sides of it and an outlet opening in place of its intersection with the tower. All eight apertures are identical in terms of dimension, each having an area of 1 m^2. The tower's openings have their barycentre at 7 meter and the room openings have theirs at 1.5 meter form ground level.

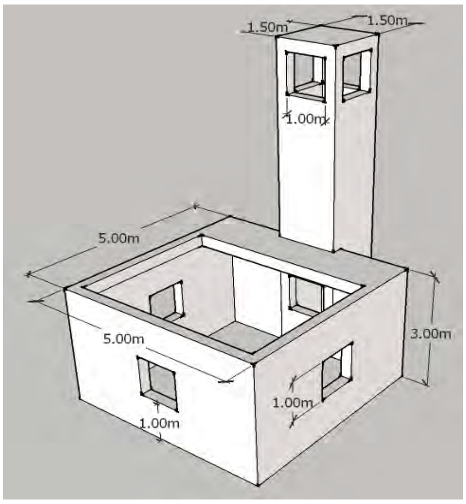

Figure 1. The model of the room and tower assessed in SPERAVent.

All these transparent surfaces have matching thermal characteristics such as 1.2 W/m^2K for thermal transmittance, 0.5 for solar factor, 0.8 for frame factor and 0.5 for shading factor of mobile screens.

The mechanical ventilation is absent and the infiltration is assumed a minimum of 0.5 vol/h. The apertures operate automatically in function of air temperature. The airflow direction _from wind tower's openings to room's apertures or vice versa_ depends on the pressure difference, i.e. on air temperature difference and wind force combined, between inlet and outlet openings. For the purpose of this calculation, no external obstruction to wind is considered.

Assessment of orientation

In the first set of simulations, the model's orientation and its relevant exposure of apertures were studied by alternatively opening one of four tower apertures, one of three room windows and rotating the model along four main geographical axis. The following table summarises the 48 combinations.

According to Table 2, the optimum orientation for both Milan and Rome is when the tower is located in southern side of the room and the open apertures are the northern window of the room and the southern opening of the tower.

Table 2. Effect of orientation (model layout, direction of tower's opening and room window aperture) on energy saving percentage. (* highest energy saving, ** lowest energy saving)

Model layout	Direction of tower aperture	Direction of room aperture	Number of airflow deviations	Energy saving percentage Milan	Energy saving percentage Rome
	W	E	3	85.92	62.09

	E	N	3	88.06	61.89
	E	E	2	90.05	59.69
	E	W	2	92.78	67.08
	E	N	3	88.12	61.89
	E	S	3	88.07	64.17
	N	S	3	85.32	58.96
	N	N	3	81.63	50.27
	N	W	2	92.16	66.19
	S	W	2	93.03	67.74
	S	N	3	88.24	64.74
	S	S	3	81.63	50.27
	W	S	3	87.52	62.34
	W	N	3	87.51	62.87
	W	W	2	90.14	59.68

Depending on the direction of the openings, the airflow is subject to a number of deviations. As reported in Table 2, for each model orientation, when there are fewer deviations, the energy saving is higher. The worst cases are those where the inlet and outlet apertures face the same direction and thus the outlet air by stack effect faces the incoming wind.

Table 3 and 4 summarise the cooling demand for the two cities in five warmer months of the year, the sum of which makes the net annual cooling demand in Milan's optimum case to reduce from 1015.69 kWh/year to 69.60 kWh/year by means of controlled natural ventilation (CNV). In best case of Rome, these numbers are 2040.82 kWh/year and 616.09 kWh/year respectively.

Table 3. Monthly cooling demand (kWh/month) in absence and presence of CNV system for Milan.

	May	June	July	August	September
Presence of CNV	0.0	0.73	26.97	38.6	3.3
Absence of CNV	0.0	132.15	413.44	334.18	135.92

Table 3. Monthly cooling demand (kWh/month) in absence and presence of CNV system for Rome.

	May	June	July	August	September
Presence of CNV	0.0	16.2	173.08	327.36	99.46
Absence of CNV	17.11	266.93	668.33	761.97	305.9

Assessment of internal heat capacity

For this part of the assessment, the best performing orientation has been selected as the reference where for both Milan and Rome the main orientation was north, and the openings were facing south on the tower and north on the room. In the previous assessment with medium-weight opaque elements (walls, floor and ceiling) corresponding to an internal heat capacity (IHC) of 155 kJ/m^{2}K and thermal transmittance of 0.3 W/m^{2}K, the cooling energy reduction were 93.15% and 69.81% for Milan and Rome respectively.

Table 4. Effect of heat capacity of opaque surfaces on cooling energy requirement and reduction.

Internal heat capacity (kJ/m^{2}K)	Milan: Net cooling requirement (kWh/year) Without CNV	Milan: Net cooling requirement (kWh/year) With CNV	Milan: Energy reduction (%)	Rome: Net cooling requirement (kWh/year) Without CNV	Rome: Net cooling requirement (kWh/year) With CNV	Rome: Energy reduction (%)
85	1069.04	153.22	85.67	2108.01	741.54	64.82
155	1015.69	69.60	93.15	2040.82	616.09	69.81
225	985.96	36.86	96.26	2004.19	557.02	72.21

Considering light-weight elements with an IHC of 85 kJ/m^{2}K and the same thermal transmittance of 0.3 W/m^{2}K, the cooling demand reduction would become 85.67% in Milan and 64.82% in Rome. Whereas, using heavy weight elements with 225 kJ/m^{2}K of IHC and equal thermal transmittance, would increase the reduction percentage to 96.26% and 72.21% for the two cities correspondingly.

Obviously, any increase in the heat capacity of the walls, would decrease the cooling energy requirement of the whole model, as shown in Table 4 –net cooling requirement. However, in presence of a controlled natural ventilation (CNV) system, the decline is greater and consequently the energy reduction percentage is higher in case of a model with higher thermal mass value.

Conclusion

A conceptual model of a one-sided wind tower and a room has been assessed in SPERAVent software for Milan and Rome with humid subtropical (Cfa) and hot-summer Mediterranean (Csa) climatic conditions and has shown circa 93% and 70%, respectively, of saving in cooling demand, as a maximum. Further theoretical and experimental investigations are needed in order to evaluate the applicability of a wind tower system in the whole European territory.

Based on statistical studies for the Mediterranean area (Chiesa et al, 2015) and Central and Southern Europe (Grosso et al, 2015), it is already possible to estimate the European zones which have the highest potential of applying a controlled natural ventilation technique as a function of wind force. In these zones, the application of a wind-tower system in new building projects should be easy, being mainly a matter of applying the correct knowledge and methodology in the design process. More difficulties might be found in retrofit projects, where orientation of buildings and openings, which were found to be in the present study the parameters most affecting the energy performance, are very much constrained by the site context.

Abstract: A difficulty in establishing to what extent innovative windows are efficient is observed, therefore, there is a need to generate an experimental methodology for performing the analysis of the systems. First, the design and construction of an innovative glazing system is carried out, whose performance will be evaluated. The design criteria of this prototype are to optimize the use and storage of passive solar gain. The evaluation of the performance of the system is carried out by means of an experimental comparative analysis between the system and a standard element. To carry out this analysis, two equal experimental cells have been designed and constructed, where a constant internal temperature is maintained, supported by a heat pump. These cells have been monitored during nine months, obtaining consumption, temperature, and relative humidity data. Savings on consumption of heating in winter are up to 48% during a high radiation winter day. The objective of harnessing solar radiation is reached and is reflected in monthly reduction consumption up to 25% on heating in the cold months without penalizing cooling consumption in summer. Performance of the active glazing panel is confirmed to be optimal according to the design strategies for the climate of Madrid.

Keywords: windows, glazing, energy efficiency, experimental cells.

Introduction

Buildings and their environment are responsible for 40% (Enerdata, 2012) of the overall energy consumption in European countries. It has been identified as the sector with the largest energy saving potential (circa 75%) (Ristori, 2013). The reduction of energy demand on buildings, especially taking advantage of passive solar gain wasted so far, is one of the greatest challenges to achieve the objectives of H2020 strategy related to CO2 emissions, energy demand, and the share of renewable energy (EEFIG,2015) within this sector.

Energy Efficiency is one of the greatest energy resources, considering the potential effect over energy dependency from external countries. Within the European Union, four main directives have been developed to set the roadmap for the built environment, towards the objectives to reach by 2050: (EU,2002): Energy Performance in Buildings (EPBD), (EU,2009): Use of renewable energy, (EU,2010): Net-Zero Emissions Buildings, and (EU,2012): New directive for Energy Efficiency in Buildings.

In Spain, IDAE data (1) indicates that between 25% and 30% of our heating needs are due to the heat losses that arise through windows.

Regarding energy consumption associated with windows, several studies indicate their high potential for savings (Avasoo et al, 2004) *"The energy saving potential in the CPIV-FIZ studies, only by upgrading glass U-values from 5,7 and 2,9 to1,6W/m2K could save 1,115*

MGJ (million gigajoules or 26 million Toe (Tonnes of oil equivalent)each year. The CO2 reduction was estimated to 82 million tonnes per year.”

The INVISO (Industrialized sustainable Housing) Project aimed to develop a new industrialized, light, sustainable and energy efficiency construction system. It should be a competitive system especially focused on its effect on energy savings and associated GHG emissions. (Vega, S. et al, 2011).

The system designed is a combination of 3D and 2D modules; shown in figure 2. The SD10 prototype, presented in figure 3, is a basic unit of the INVISO system, built at the UPM Campus in Madrid.

Figure 1. On the left INVISO industrialized construction system Project. On the right unit Prototype SD10.

In this context the active modular glazing panel has been designed, which is a 2D glazing module for the south façade.

Figure 2. Active modular glazing panel components.

The system integrates a doble galzing area, a heat exchanger and a solar control devise. The active elements are controlled according to the user needs and the exterior climate conditions. Components of the system are shown in figure 2: double window with an intermediate air chamber, an exterior sun protection, two heat exchangers composed of PCM (phase change material, Rubitherm 21ºC) and four air renovation grids. The sun protection and the grids will operate, allowing the movement of the air through the chamber and through the heat exchangers and allowing or blocking the access of solar radiation.

The air is pre-heated or pre-cooled by passing heat exchangers before accessing the dwelling; In addition, these exchangers absorb the energy that is released later reducing the air conditioning needs of the building.

Establishing to what extent this innovative glazing system is efficient is the objective of this work; therefore, an experimental research for performing the analysis of the efficiency has been carried out.

Methodology

The active modular glazing panel is designed and built for experimental prototype SD10. However, a difficulty to isolate the effect of the system to establish to what extent it is efficient is observed, therefore, a sample is built to be comparatively evaluated to a conventional window in two experimental cells where the variables and its effects are isolated.

In order to carry out this analysis, two identical adiabatic spaces (cells) have been designed and built; on south façades the prototype and the reference windows are placed, being the only surfaces with a significant heat transfer.

Cell 1 will be the space in which the innovative system (Prototype) is placed, and in cell 2, the reference window is placed. In these spaces a constant interior temperature is maintained with the support of a heat pump and the consumption of air conditioning is counted. Measurement was carried out during a period of 9 months, from July to March, analyzing and comparing the results, thus obtaining results of the real behavior of the system. The experimental cells are designed with the aim of creating spaces subject to similar external conditions, where comparative experimentation is possible. This is achieved by designing two spaces of dimensions 3.30 m X 3.30 m X 3.30 m, dimensions as similar as possible to a living space, adapting to limited space availability. They have a total insulation of 51 cm thickness in all its faces and a transmittance of 0,072 W /m2 K.

Monitoring

In cell 1 in the interior sensors of temperature, relative humidity and CO_2 are placed. For the analysis of the air renovation, five anemometers are placed, one in the extractor and another four in each one of the four grids. 24 thermocouples are placed in different elements: in the center of each surface of the module, one on the outside and one on the inside, one close to each anemometer, in order to analyze the operation of the thermal buffer created by the chamber. In the center of each glazing, inside and outside thermocouples are placed. To determine the efficiency of the heat exchangers, three thermocouples are placed in each one, one close to the outer face, another in the center and the third one in the interior. Finally, a pyrometer and a temperature sensor are placed on the outside. These elements are used for the double purpose of recording data and activating the active elements of the system: grids and blind.

In the same way as in Cell 2, temperature, relative humidity and CO_2 sensors are located in the interior. For the analysis of the air renovation, two anemometers are placed, one in the extractor and another next to the aerator grille located in the standard window, 12 thermocouples are placed: 2 thermocouples are placed in the center of each surface of the module, one on the outside and one on the inside, in this case no thermocouple is placed next to the anemometer as the air enters directly from the outside. In the center of the glazing element, one thermocouple is placed inside and one outside.

In addition, data from a weather station is taken.

The conditions established in both experimental cells are: indoor temperature is programmed to be maintained at 22 - 23 ° C; both heat pumps are on 24 hours, one air renovation is carried out per hour.

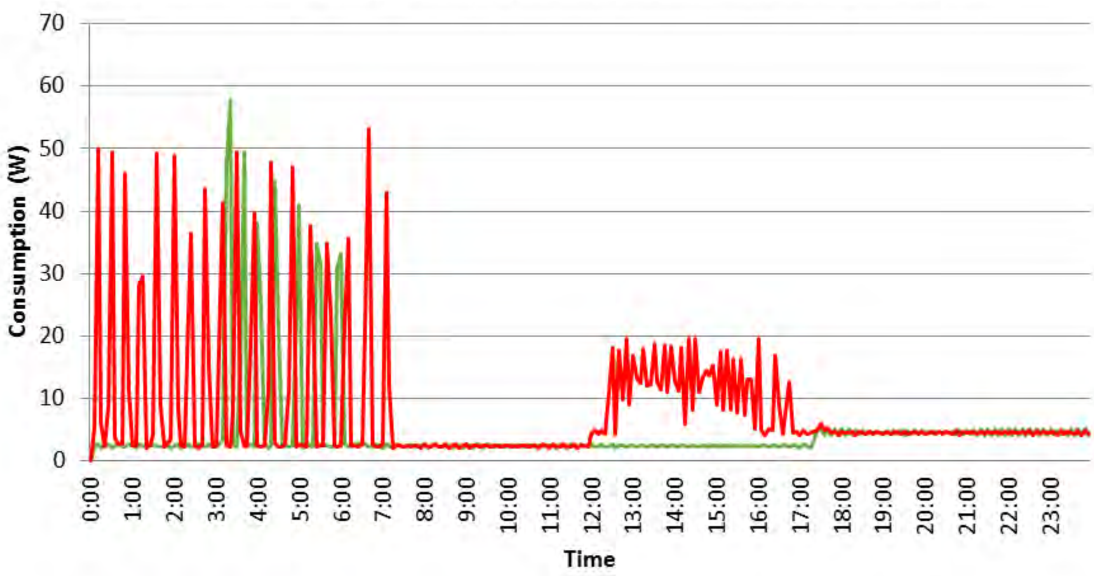
The drive of the systems is established according to the following set points: Text> 22ºC and Solar radiation> 800 W / m2

Results

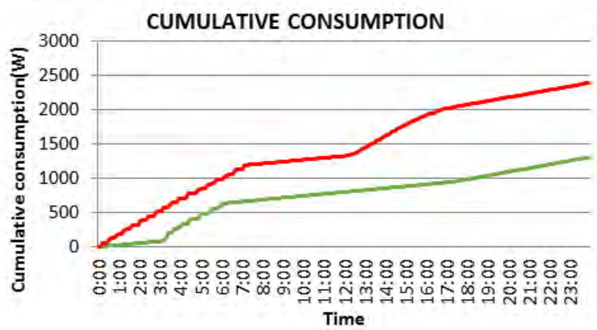
For nine months the HVAC consumption is obtained, the accumulative consumption is calculated and contrasted with interior and exterior temperatures.

Table 4: Daily Consumption results.

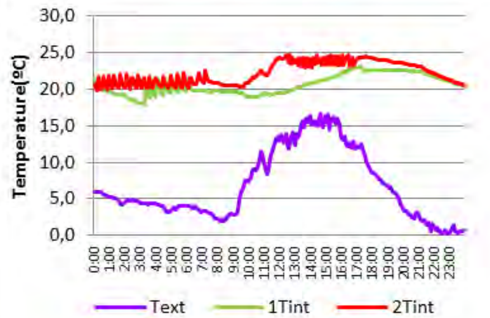
Jan. 28th HVAC Consumption. On green prototype window results, on red reference window data.



January 28th Cumulative consumption



January 28th temperatures



In a cold and sunny day (Example: January 28th) a reduction of up to 48% of consumption is obtained.

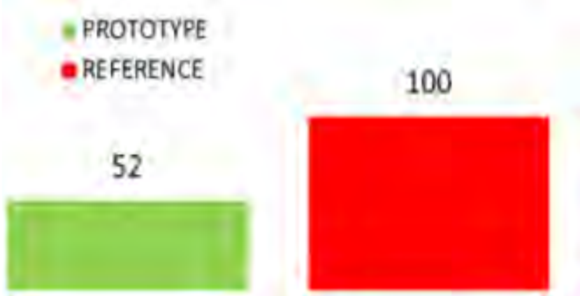


Figure 4. Reduction of consumption per day. (Example: Jan. 28th)

Bellow consumption reduction for each month is obtained.

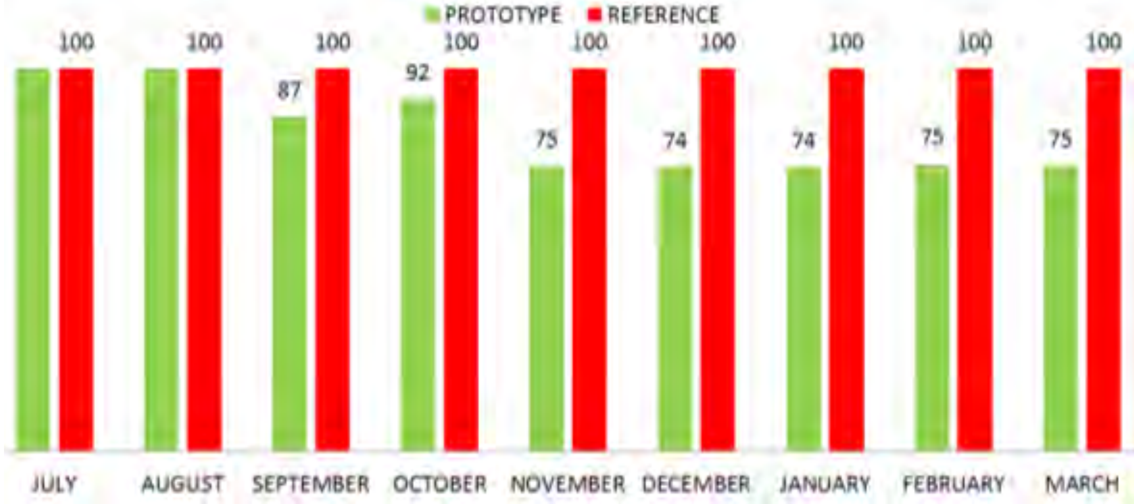

Figure 5. Monthly Consumption Results.

Results regarding the glazing system performance:

The analysis of data of different selected days is performed in order to confirm the system is functioning according to the design strategies:

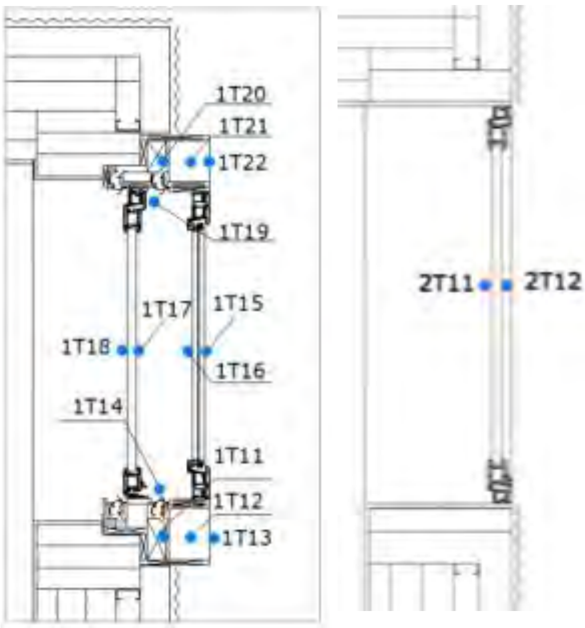

Figure 6. Thermocouples position in Prototype and reference window.

Summer position

In the air chamber a difference of 10ºC between the inner faces of the glazing is reached (1T15-1T17), which confirms the effect of the thermal buffer. Regarding the comparison between the prototype and the reference window a difference of 10ºC between sensors 1T17 and 2T12 is also confirmed.

Regarding the Heat Exchanger, the upper exchanger registers temperatures 15ºC higher than the lower one (Figure 7) and the upper and lower thermocouples of the chamber register ΔT=4ºC, the anemometers register the increase of speed in the hours of higher temperatures. Everything indicates the chimney effect caused by the design is working.

Winter position, low solar radiation:

In the air chamber there are between 4 and 9 ºC of difference between the sensors of the chamber, observing the thermal buffer effect. A similar ΔT is also confirmed between the 1T17 sensor of prototype and 2T12 sensor of reference window.

Regarding the Heat exchanger even with low solar radiation, the upper heat exchanger registers temperatures up to 8 ºC higher than the lower heat exchanger (Figure 7), and the thermocouples 1T14 and 1T19 in the chamber record a temperature increase of between 2 and 5 ºC.

Winter position, high solar radiation:

The chamber acts as a solar capturing element. The temperature in the 1T17 thermocouple is between 7 and 11 ºC higher than that of the 1T15 thermocouple.

1T17 sensor in the prototype presents a temperature 10ºC higher than 2T12 sensor of reference window.

Both Heat Exchangers register temperatures above the outside temperature, the upper one registers temperatures up to 13ºC above the lower and the thermocouples 1T14 and 1T19 in the chamber register a temperature increase of up to 12ºC. (Figure 7)

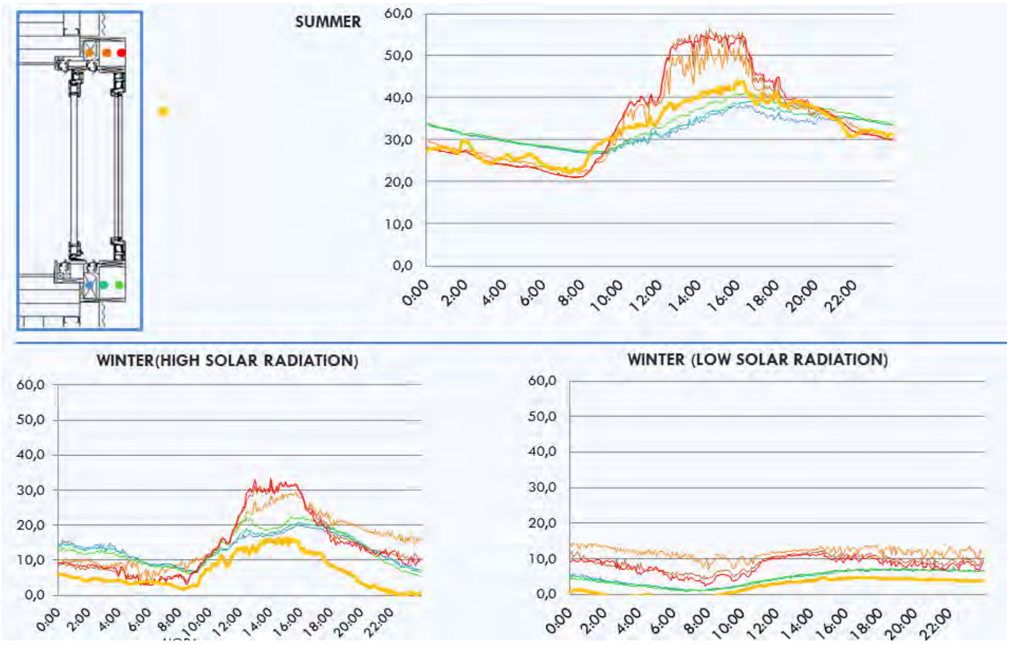

Figure 7. Thermocouples data in Heat Exchanger.

Conclusions

It is observed that the greatest consumption occurs in the summer months due to refrigeration, followed by the heating consumption during the winter months. In December, January, February and March, the reduction in HVAC consumption is 25% in Prototype cell in relation to Reference Cell, due to the use of solar radiation. In months September, October and March there is also a reduction of between 5 and 15%. In summer the consumption of both cells is equal.

The objective of using solar radiation is reached and is reflected in the reduction of consumption in heating up to 25% in heating in the cold months without penalizing the consumption in refrigeration.
The scheme of operation of the prototype, in view of the results, can be considered optimal for the climate of Madrid.
In terms of the performance of the active glazing panel, by analyzing the monitoring data of the selected days, the operation of the active glazing panel is confirmed according to the starting strategies defined for its design. The effect of the thermal buffer is confirmed by checking the surface temperatures of the glazing.

Table 5. Surface temperatures of the glazing

	Summer	Winter (high radiation)	Winter (low radiation)	Autumn (high radiation)	Autumn (low radiation)
ΔTmax	-10 ºC	+20 ºC	-9 ºC	+10 ºC	-4 ºC

The Heat Exchanger registers corresponding temperatures for optimum operation at different times of the year.

Table 6. Heat Exchanger temperatures.

	Upper Heat Exchanger			Lower Heat Exchanger		
	Tmax	ΔT day	ΔTmax	Tmax	ΔT day	ΔTmax
August 10th	55 ºC	34 ºC	10 ºC	41 ºC	13 ºC	4 ºC
October 11th	40 ºC	23 ºC	4 ºC	33 ºC	11 ºC	2 ºC
October 18th	24 ºC	11 ºC	4 ºC	22 ºC	5 ºC	1,5 ºC
January 7th	14,5 ºC	7 ºC	6 ºC	7,5 ºC	6 ºC	1 ºC
January 28th	33,6 ºC	25 ºC	6 ºC	22 ºC	15 ºC	3 ºC

Design to Thrive

The Sustainability Assessment of Window Design in Patient Rooms in Hospitals

Nazanin Eisazadeh[1] and Karen Allacker[1]

[1] Architectural Engineering Unit, Department of Architecture, Faculty of Engineering Science, KU Leuven, Belgium, nazanin.eisazadeh@kuleuven.be

Abstract: Facades are a crucial interface between the external conditions and the required conditions inside a building. Using glazing in the building envelope provides daylight, views and ventilation. Windows can hence contribute significantly to indoor environmental quality and impact patients' recovery and length of stay in hospitals. Even though windows have many advantages the energy exchange through glazing has an important impact on heating and cooling loads in buildings. Window performance has improved over the years by using double and triple glazing, low-e coatings and argon and krypton gas fill. More recently, novel glazing technologies have emerged that promise further improvement of window performance; examples are smart windows, advanced coatings etc. This paper investigates the role of the glazing type and window design on energy efficiency and daylighting in a sample patient room. A preliminary study has moreover been performed on the environmental impact of these windows from a life cycle perspective. Simulation of the energy consumption and daylighting were conducted using the DesignBuilder software. Designing and evaluating window systems becomes complicated when energy efficiency, daylighting, comfort, environmental impact and cost are considered simultaneously. Hence, this paper is an initial step towards such a holistic approach.

Keywords: Sustainability, Energy efficiency, Daylighting, Environmental impact

Introduction

In the European Union 40% of total energy consumption is due to the building sector (Stazi et al, 2012). Hospitals are considered one of the most energy demanding building types and patient rooms occupy the largest space of hospital buildings (Sherif et al, 2014). Recently, more attention is being paid to comfort and potential non-visual effects of daylighting on well-being, productivity, sleep quality, stress reduction, etc. (Choi et al, 2012) (Vanhoutteghem et al, 2015). As windows play a major role in both energy loads and quality of the indoor environment, analysing the role of window design on building sustainability is seen essential.

A major issue when assessing the sustainability of windows, is their energy performance. The energy performance of windows is influenced by several factors: U-value (thermal transmittance), SHGC (solar heat gain coefficient), climatic conditions, orientation and building parameters (Vanhoutteghem et al, 2015). The U-value indicates the rate of heat transfer through a window (Jaber and Ajib, 2011) and SHGC is the fraction of solar radiation directly transmitted through a window and inward flowing solar energy absorbed by the glazing (Carlos and Corvacho, 2015). If the building is highly insulated the main external heat gains and losses occur through the window, making the task of designing the window become more challenging.

When assessing the sustainability of windows it is not sufficient to evaluate the influence of windows on the energy performance of the building and the need for artificial lighting. The full life cycle of the window should be considered, including the environmental impact related to material production, maintenance and end-of-life treatment. LCA (life cycle assessment) is an internationally accepted method to quantify these life cycle environmental impacts.

In order to avoid high energy loads, selecting the appropriate size, proportion, shape, location and type of window along with the orientation and shading are a fundamental part of early design stage decisions, and are difficult to change later on. This can be achieved by obtaining an integrated performance analysis where the link between various window design parameters and their combined effect on energy consumption, comfort, environmental impact and cost are considered. This paper presents an integrated approach to find a balance between increasing energy efficiency while maintaining a comfortable and healthy indoor environment with the least environmental impact. The methodology combines energy simulation, LCA and daylighting analysis.

State of the art

While there are many studies on window design with regard to energy consumption, comfort and lighting in office buildings (Ochoa et al, 2012) (Susorova et al, 2013) (Tzempelikos and Athienitis, 2007) these topics have been less explored in hospitals (Alzoubi et al, 2010) (Sherif et al, 2014). Literature review showed that previous research on windows performance mainly focus on energy, daylighting, thermal comfort (Manz and Menti, 2012) (Ochoa et al, 2012) (Sherif et al, 2014) (Skarning et al, 2016) (Stegou-Sagia et al, 2007) (Tzempelikos and Athienitis, 2007) (Vanhoutteghem et al, 2015) and less attention is paid to the environmental aspects (Citherlet et al, 2000) (Papaefthimiou et al, 2009).

Designing and evaluating window systems becomes complicated when energy efficiency, daylighting, comfort, environmental impact and cost are considered simultaneously and all window design parameters (glazing properties, frame, size, shading…) are taken into account. Hence, this paper is an initial step towards such a holistic approach.

Methodology

A simulation analysis was performed to investigate the effect of glazing type, orientation and shading on energy consumption, environmental performance and daylighting in a patient's room in a hospital. This section presents the parameters used and assumptions made for this analysis.

The simulation analysis was performed assuming a base case as reference and varying one parameter at a time in the model. This approach is chosen to compare the effects of one parameter in detail while all the other parameters are fixed. The sample patient room was used as the base case and glazing, orientation and shading as the variable element. For each variation, the operational energy, the life cycle environmental impact and the daylight availability were analysed.

Window system

The aim of the analysis of the window system was to analyse the overall performance of glazing systems in (1) existing buildings (basic scenario) compared to (2) a glazing system with improved characteristics in terms of light and UV transmitted and (3) a glazing system with improved characteristics in terms of solar control and heat resistance. The second type of glazing is selected for its potential positive impact on patient's health and the third type of glazing is selected based on its beneficial influence on heating demand and overheating issues.

The double glazing selected consists of two 4 mm glass panes and a 15 mm spacer with argon as gas fill. Additional optical and thermal properties of the selected double glazing are presented in Table 1.

I. Basic window: Base for comparison; the U-value and SHGC value are similar to double glazing used in existing buildings
II. Low Iron window: High light and UV transmission
III. Coated window: Solar control and high thermal insulation

Table 1. Properties of the double glazing

Glazing	Light Transmission	SHGC	U-value (W/m^2K)	Glazing Characteristic
I	0,82	0,79	2,50	Uncoated
II	0,84	0,84	2,50	Low Iron
III	0,72	0,53	1,10	Coated

The shading devices considered in the analysis are overhangs of 0,50 m for the South orientation and louvres and inside roller shades for the East and West orientations. The louvres have 7 blades with 0,20 m spacing and 0,20 m depth; the roller shade has a 0,40 solar transmittance and 0,45 reflectance with 0,1 conductivity (W/mK).

Model specifications

An actual patient room plan and construction detail from a hospital under construction in Belgium was used for the simulation. The room has one external wall with a single window; all other surfaces are assumed adiabatic (absence of thermal exchange). The external wall measures 4,0 m (width) x 6,0 m (depth) x 3,0 m (height). The window is 1,5 m x 2,4 m (height, width) with a 0,8 m sill height. U-Value of the external wall equals 0,218 W/m^2K and the wall is 0,42 m thick. Room heating and cooling set-point temperatures were assumed to be 22°C and 24°C respectively, relative humidity between 30 to 60% and mechanical ventilation was set to 2 (ac/h); these numbers are in accordance with standards provided for patient rooms (Environmental Design: CIBSE Guide A, 2006). Internal gains from people (104 W), lights (2,80 W/m^2) and equipment load (3,58 W/m^2) are modeled based on a 24 hours x 7 days occupancy schedule. The three windows have been simulated in this patient room: Room A (basic window), Room B (low iron window) and room C (coated window).

The simulations are made for the three models with windows facing North, South, East and West; with/without shading. No external obstructions were taken into account. EnergyPlus weather data for Brussels (latitude 50,90 and longitude 4,53) was used for the calculations. Simulation of the energy consumption and daylighting were conducted using the DesignBuilder software; DesignBuilder uses EnergyPlus as energy simulation engine and Radiance for daylighting. The environmental impacts were calculated at material level with Simapro (LCA software) and at building level with the KULeuven-MMG tool.

MMG is an expert calculation tool for the quantification of the environmental performance of building elements, specific for the Belgian context. In this tool, the generic LCI (life cycle inventory) data (Ecoinvent) are adapted to the Belgian context. The impact assessment method in the MMG methodology combines environmental impact categories from the CEN standard (EN15978), referred to as CEN indicators, and additional ones in line with the ILCD handbook, referred to as CEN+ indicators. The CEN indicators include global warming, ozone depletion, acidification, eutrophication, photochemical ozone creation, abiotic depletion resources-elements, abiotic depletion-fossil fuels and the CEN+ indicators cover human toxicity, particulate matter, ionising radiation: human health, ionising radiation: ecosystems, ecotoxicity, water scarcity, land occupation, land transformation. To allow for a decision-oriented selection, the characterised values for each individual environmental indicator can optionally be multiplied with a monetisation factor. This factor shows the extent of the potential damage to humans and/or the environment, expressing it in a financial amount for the purpose of avoiding potential damage or settling any damage sustained (Environmental profile of building elements, 2013).

Step 1: energy analysis

The aim of the first step was to calculate and compare the annual energy consumption expressed in kWh associated with heating and cooling for all 27 cases.

Step 2: environmental impact

The goal of this step was to determine the environmental impact associated with production, maintenance and disposal of the three glazing types and to calculate and compare the life cycle environmental impact of the rooms. Ecoinvent was used for the LCI data of the basic double glazing LCA. The coated and low Iron glazing were however not available in Ecoinvent. For these, EPD (environmental product declaration) data were used for the impact of the CEN-indicators related to the production phase, while the CEN+ indicators were approximated by the impact of the double glazing. For the modelling at the room level, the operational energy (heating, electricity) was estimated with DesignBuilder and imported in the MMG tool to calculate the related environmental impacts.

Step 3: daylighting analysis

In this step a simulation-based daylighting analysis for the rooms in an overcast sky condition was carried out. The target illuminance for this case is 125 lux and the reference plane is the patient bed level plane (0,90 m height). It should be noted that one third of the room is service area (across the window wall) and does not require daylighting.

Results and discussion

Results step 1: energy analysis

The annual energy consumption in all models was dominated by heating, than followed by cooling as shown in Figure 1 and 2. The annual energy consumption for Room A and Room B are similar and significantly higher than for Room C, in all orientations without shading devices. Figure 3 and 4 highlight the fact that basic and low Iron windows allow for more solar gains and higher heat loss compared to the coated window. The percentage of energy savings from coated glazing compared to the other two glazing types ranges from 19% to 23% in all orientations. Among all models, the North orientation has the highest heating energy as a result of low incident solar radiation (low solar gains). The cooling energy is 13% to 15% less in East oriented models compared to West oriented models under same conditions due to higher temperatures and solar radiation in the afternoon.

Shading has a major impact on cooling energy with savings from 25 to 40% in all orientations (no shading in north). The results show that the cooling energy of Room A and Room B with shading devices is close to or lower than Room C without shading devices.

Results step 2: environmental impact

In this step the life cycle environmental impact was calculated. The findings show that the coated window has a lower environmental impact compared to the other two window types. Room C has the lowest environmental impact due to the energy saving provided by coated glazing. From Figure 5 and 6 it is possible to deduce that low Iron window and Room B lead to the highest environmental impacts, although the differences are minor/negligible compared to the basic window and Room A.

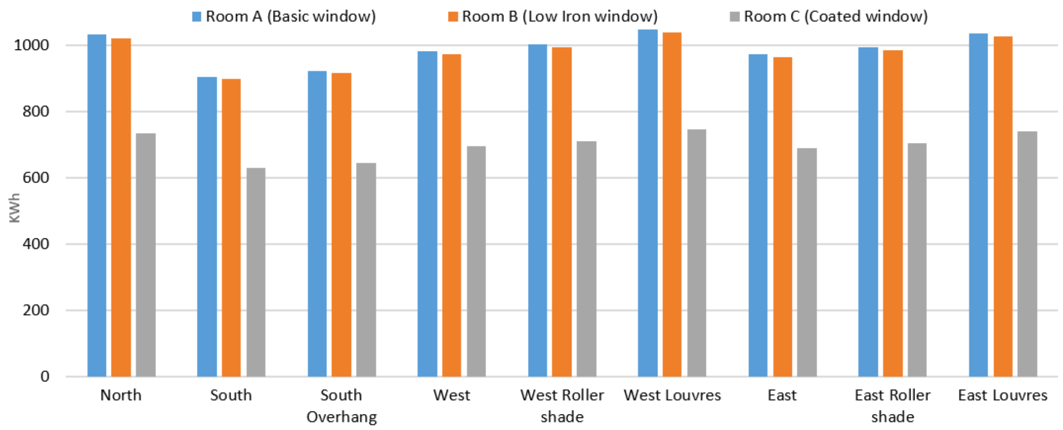

Figure 1. Annual heating energy

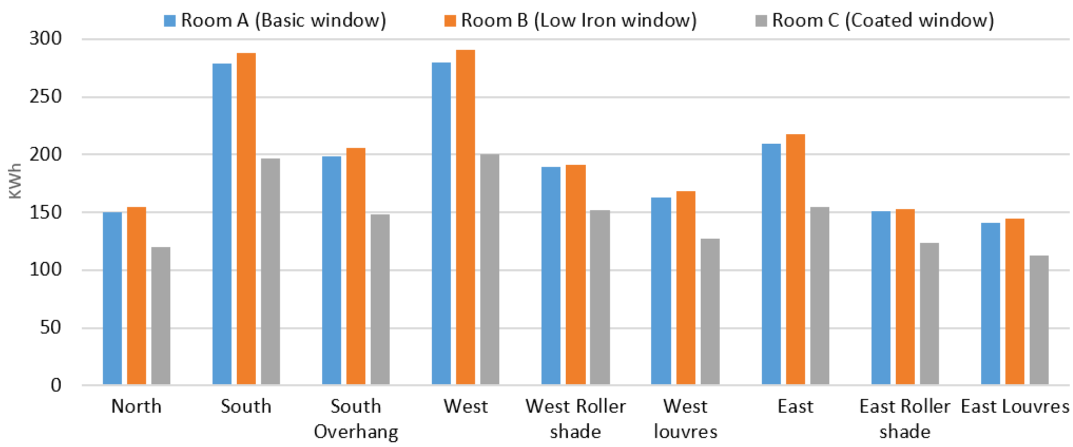

Figure 2. Annual cooling energy

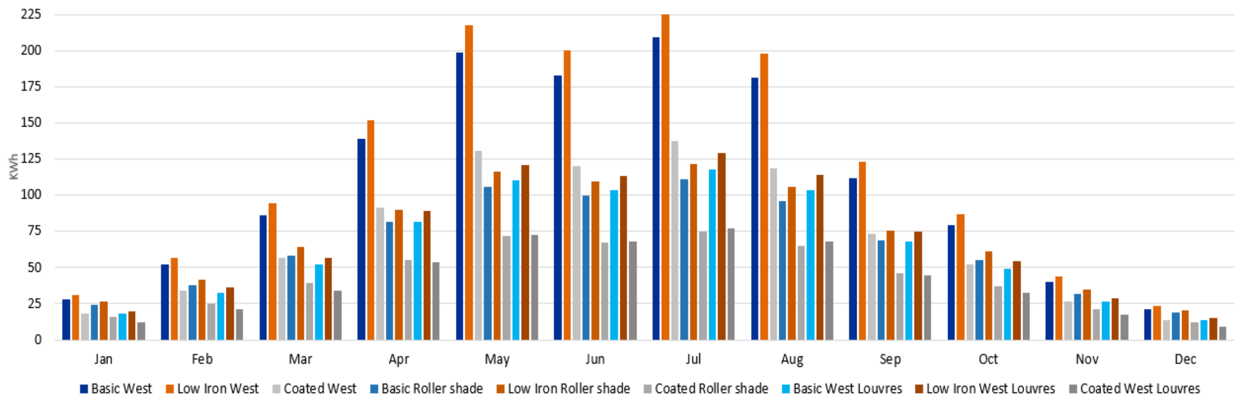

Figure 3. Solar gains windows in West with/without shading

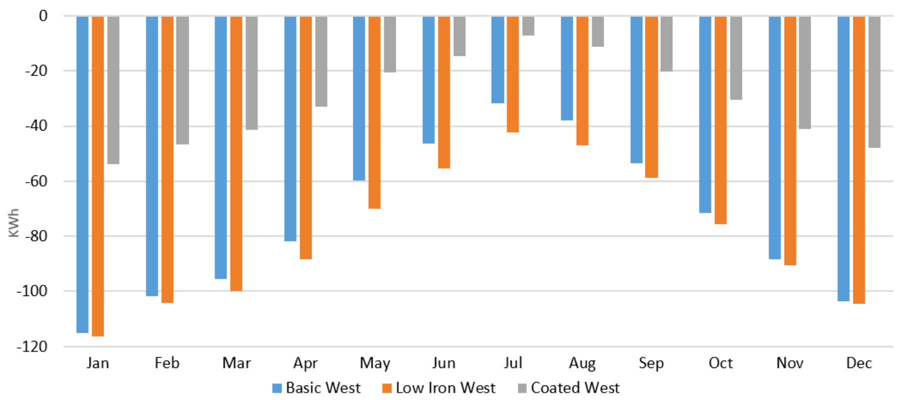

Figure 4. Heat Loss in West oriented windows

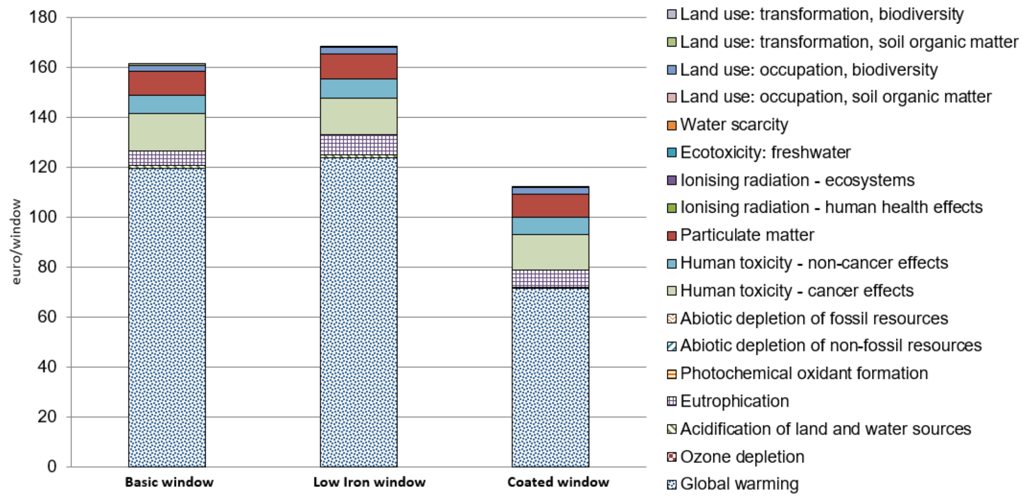

Figure 5. Windows life cycle environmental impact

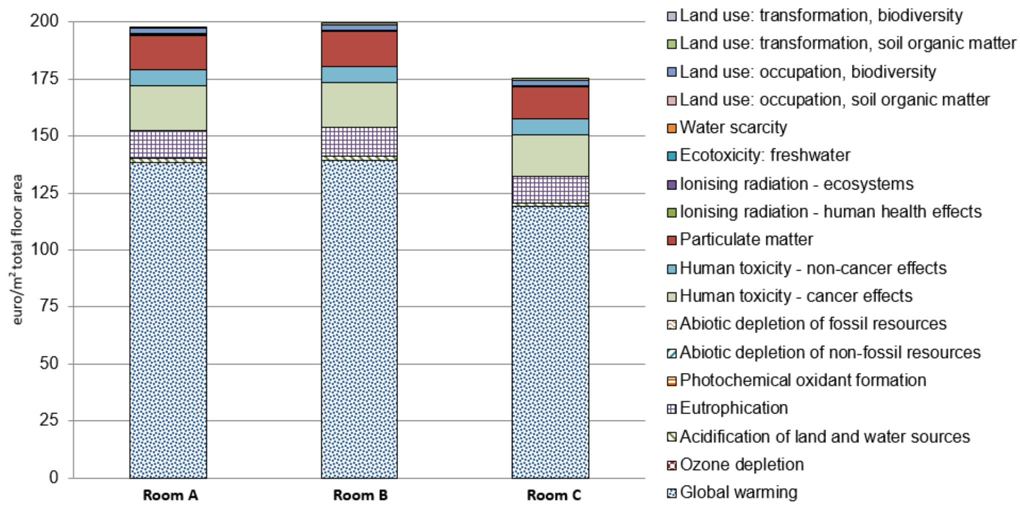

Figure 6. Patient rooms environmental impact

Results step 3: daylighting analysis

The spatial patterns of daylight presented in Figure 7 suggest that the daylight area extends across half of the room adjacent to the window in models without shading. The figure shows an overlit area (pink) near the windows (illuminance level is ten times more than target).

The average DF (daylight factor) is a measure of the amount of skylight in a room. An average DF of 5% or more will ensures a substantially daylit interior and an average below

2% generally makes a room look gloomy and artificial lighting is likely to be needed most of the day (Yarham, 1999). As shown in Table 2 the values are mostly above the recommended minimum DF of 2%. North oriented models achieve good DF averages and no discomfort glare by direct sunlight. The overhang in South oriented models reduce the solar gains and cooling energy in summer but keep the DF within an acceptable range. Fixed louvres in the East and West oriented patient rooms significantly reduced the DF. The findings suggest that using active shading devices in West and East orientations may be a better option for satisfying both energy saving and daylighting criteria at the same time. As expected Room B with low Iron window has the highest DF averages on all sides due to high light transmittance but the difference compared to the other models is rather small.

Table 2. Average DF of models

Average Daylight Factor (%)	Without Shading				With Shading		
Orientation	North	South	East	West	South	East	West
Room A (Basic window)	3,77	3,83	3,82	3,79	2,90	1,47	1,51
Room B (Low Iron window)	3,89	3,94	3,96	3,86	2,98	1,53	1,57
Room C (Coated window)	3,22	3,30	3,31	3,26	2,50	1,28	1,31

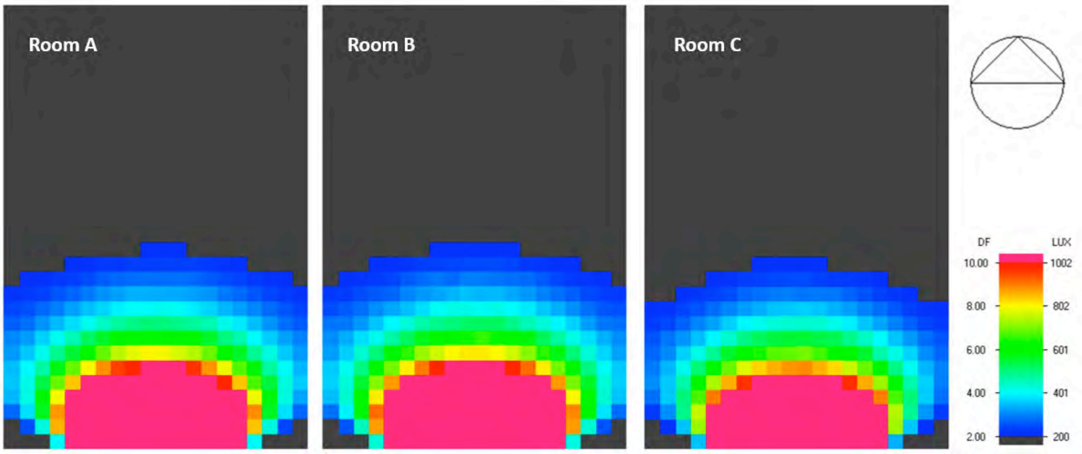

Figure 7. Illuminance map of south oriented rooms without shading

Final results

In Belgium the main factor for window selection to date is influenced by the heating loads but the results demonstrate that the effect of the window on the cooling loads should be considered as well. From the three windows assessed, the models with the coated window have the best overall performance; showing the importance of glazing characteristics in window design. The simulations moreover highlighted that a solar control coating allows for efficient daylighting without the risk of overheating.

The models with the low Iron window have the lowest overall performance; the high solar gains in summer increase cooling energy approximately by 30% compared to models with the coated window. Additionally, the illuminance maps and DF averages show that the effect of the low Iron characteristic does not particularly contribute to optimal daylighting and does not compensate for the high energy consumptions and environmental impacts.

The results moreover show that shading devices have a major impact on energy saving and daylighting and in order to achieve an overall good performance, using active shading devices in West and East orientations may be a better solution compared to fixed devices.

Conclusion

This preliminary simulation analysis was useful to evaluate the combined effect of various glazing and window design parameters on energy consumption, daylighting and the environment. This paper demonstrated that window systems have a significant impact on energy loads, environmental impact and illuminance and selecting the optimal system is a very important issue to be addressed in the early design stage. The results indicate that focusing on individual aspects is not sufficient to get a correct insight in the window system's performance and an integrated approach is required to simultaneously consider all aspects.

Abstract: Façade design has significant effects on inner conditions of spaces and also on the energy needs to achieve user's comfort. In this regard, the proportion of glazed surfaces to opaque ones plays a key role. Although the link between the fenestration ratio and energy demand for a space has been widely addressed in literature, a considerable number of these studies were based on isolated models, disregarding the effect of the urban surroundings. The aim of this paper is to provide insights on the impact of the window-to-wall ratio (WWR) on thermal energy demands taking into consideration a specific urban context. The *Eixample* district of Barcelona, with Mediterranean temperate climate, has been selected as the case study. Heating and cooling energy needs have been evaluated for a single residential space by means of computer simulations in Design Builder for different positions within the tissue. Results show that, from a thermal point of view, the design of façade openings within an urban context should vary depending on the orientation and the degree of obstruction, as a reflection of the differences in energy balance within the building envelope.

Keywords: Window-to-wall ratio, Mediterranean climate, Energy demand

Introduction

Building envelope, as the filter between outside and inside spaces, poses an environmental challenge for architects. Among all surfaces composing this enclosure, façades have been found to be decisive for environmental conditions inside buildings and, consequently, for energy requirements to maintain user's comfort levels.

Regarding the façade design, one of the first early-stage decisions made by designers is the proportion between glazed surfaces and opaque ones. For a particular space, this geometrical relationship may be expressed through two parameters: window-to-wall ratio (WWR) and window-to-floor ratio (WFR). Both indexes have been recurrently employed in literature to describe the link between fenestration design and inner environmental conditions regarding lighting (Bodart & De Herde, 2002; Ghisi & Tinker, 2005) and heat (Persson et al., 2006; Inanici & Demirbilek, 2000) either as individual aspects or from global perspective (Ochoa et al., 2012; Skarking et al., 2016).

One common approach for studies on the correlation between WWR and energy needs is to conduct their analyses based on a spatial model – usually a shoebox – conceived as an isolated entity. This definition of the study problem constitutes a logical starting point on the matter and allows us to provide valuable and straightforward insights for a simple, yet feasible, scenario. However, the final energy impact of windows on indoor environment not only depends on the element features itself but also on geometrical and material characteristics of the urban surroundings.

Investigations taking into consideration the effect of urban context are, though, much more limited. Some studies have been carried out defining a simplified urban context by using the endless canyon scheme. For example, Hegazy et al (2013) studied the combined effect of window size and shading device on daylight autonomy and energy consumption in Cairo. In this work, the complex balance between reducing air conditioning demands and lighting needs in the case of cooling-dominant climates was highlighted.

Despite the usefulness of the urban canyon approach, this model overlooks the 3D complexity of urban environments regarding local energy changes due to street intersections (Garcia-Nevado et al., 2016) and other non-canyon-shaped configurations (e.g. squares). In this sense, analysis based on urban tissue samples could contribute to a better understanding of the implications of urban façade design under more realistic conditions.

Based on a complex 3D environment, Fernández et al (2016) demonstrated that, results of window layout optimisation may differ depending on whether urban surroundings are taken into account or not. In the same vein, Vermeulen et al (2013) carried out an optimization analysis of the form and the façade layout for a block located in neighborhood of Paris. Results of this work suggested that, for heating-dominant climates, the optimum size of openings mainly depends on orientation and urban obstruction.

As shown, the role of façade design from an urban perspective is still in need of further research. This paper aims to provide additional insights on the impact of glazing ratio on thermal energy demands taking into consideration a specific urban context. This work focuses on a temperate climate, where heating and cooling needs have to be considered during the design process with regard to urban solar obstructions.

Method

In order to discuss the impact of WWR on thermal performance of spaces located in a specific built environment, a four-step method has been developed. First, the basic simulation model to be tested within a certain urban context is to be designed. The basic model is conceived as a single-space box with just one exterior façade where a variable-sized window will be located.

Second, the urban context where to study effects of WWR changes is to be modelled. The urban model consists of a central block - where the basic model will be integrated - surrounded by the minimum number of additional blocks which reproduce a representative sample of the chosen tissue.

Third, a parametric study of the thermal behaviour of the base model is performed in terms of WWR for the previously-defined urban model. To this end, heating, cooling and total air conditioning demands are selected as assessment parameters. These parameters will be calculated by means of computer-based energy simulations on an annual basis.

Finally, an optimisation analysis of WWR is carried out for the selected urban context. The optimisation problem consists in minimising a single objective function, in our case, global air-conditioning demands. Two optimisation scenarios are analysed on the basis of the constraints imposed to the glazing ratio solutions. On one hand, the optimisation problem is solved with no constraints about either the minimum or maximum WWR. On the other, the optimisation assessment is performed fixing a minimum WWR and applying a tolerance range on the minimum demand of a 10%.

Case study

Base model description

The base model of the present case study consists of a shoebox (width·depth·height = 6m·6m·3m) representing a sample of a single residential unit. The model is completely enclosed by adiabatic surfaces except for one, the exterior façade, where a single window is placed. The WWR of the space is parametrically defined between 0% and 100%, in 10% steps. No shading devices have been taken into consideration. Thermal features of the base model are detailed in Table 1.

Table 1. Base model features.

Façade materials	Exterior wall	Brick wall (12cm) + air cavity (5cm) + Brick wall (6cm) [U=1,92 W/m^2]
	Window	Single glass (6mm) + aluminium frame without thermal bridge break [U=5,7 W/m^2; g = 0,8]
Partitions	Horizontal	Concrete joists & ceramic blocks (20cm) + floor slab (5cm)
	Vertical	Brick wall (12cm)

Urban context definition

The *Eixample* district of Barcelona has been selected as case study. The original urban plan was conceived by Idelfons Cerdà (Cerdà 1867) in response to the unhealthy conditions of the overcrowded industrial city. It consists of an orthogonal grid of streets with 45º North orientation whose basic repetition unit was a slightly chamfered square (113x113m).

As a result of speculative processes, the *Eixample* resulted to be a much more densely built urban structure than the one initially planned. For this work, the profile of the block where the base model will be tested is defined according to regulations into force between 1932 and 1976 (CCCB 2009). During this period, highest densities and land occupations were reached posing a critical scenario in terms of solar access.

The present case study comprises a sample of 9 blocks (3x3). The base model is evaluated for several representative locations within the centre block of the tissue in order to analyse thermal behaviour differences in height. These positions correspond to the middle point of each block facet at two different levels (L1, L5) (Figure 1).

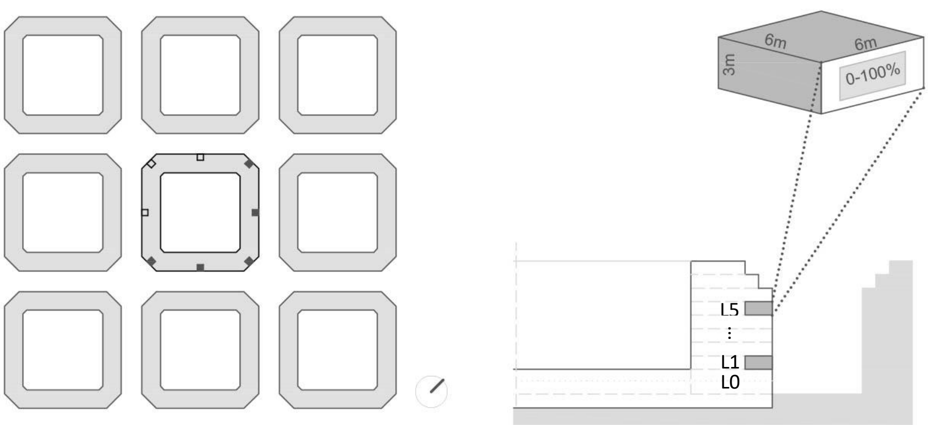

Figure 1. Plan (left) and section (right) of the *Eixample* tissue and selected locations for the test model.

Within the *Eixample* block, two kinds of façades can be identified: chamfer and long façade (Figure 2). The former, belonging to a square-shaped space, presents a lower degree of sky obstruction than the latter, pertaining to a canyon-shaped space. In sight of solar obstruction diagrams, it can be stated that more significant differences in height are found in longer façades (SW/SE, NW/NE) than in chamfer ones (E/W, N, S) regarding solar radiation availability.

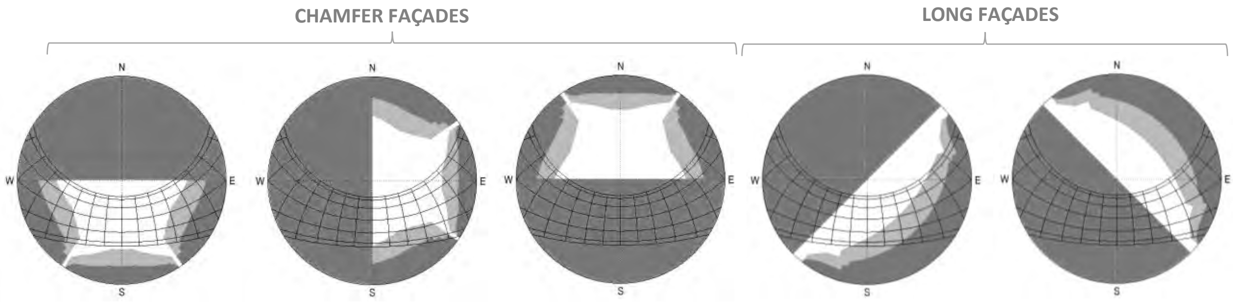

Figure 2. Solar obstructions in stereographic projection for L1 (dark grey) and L5 (light grey) for S, E, N, SE and NE façades, calculated in Heliodon (Beckers & Masset 2006).

Simulation settings

Energy simulations have been conducted using the software Design Builder v.5. This tool computes heating and cooling loads of spaces through dynamic thermal simulations based on climate data. Energy calculations in this software take into account shortwave radiation interactions with the urban surroundings (obstruction of diffuse and direct radiation + source of reflected radiation). As for longwave exchanges, the urban environment is considered to be a sky view obstacle, which is at the same temperature as the air. An overview of the simulation settings used for the present case study is included in Table 2.

Table 2. Simulation settings.

User's profile	Residential use Occupation rate 0,04 p/m^2 Schedule 100% 23-7h / 25% 7-15h / 50% 15-23h
Location	Barcelona 41°N - IWEC Weather file
Set-point Temperature	Heating 21 °C Cooling 26 °C
Free cooling	21 – 24h from June to September
Infiltrations	0,5 ren·h^{-1}
Reflectivity	R_{GROUND} = 0.4 $R_{BUILDINGS}$ = 0.4

Results and discussion

Cooling, heating and global demands

Results of air-conditioning demands depending on WWR are shown in Figure 3 for rooms belonging to an isolated block and also for an urban one. Differences in energy requirements between E, SE, NE and W, SW, NW orientations respectively are barely noticeable on an annual basis; therefore, only the former have been depicted.

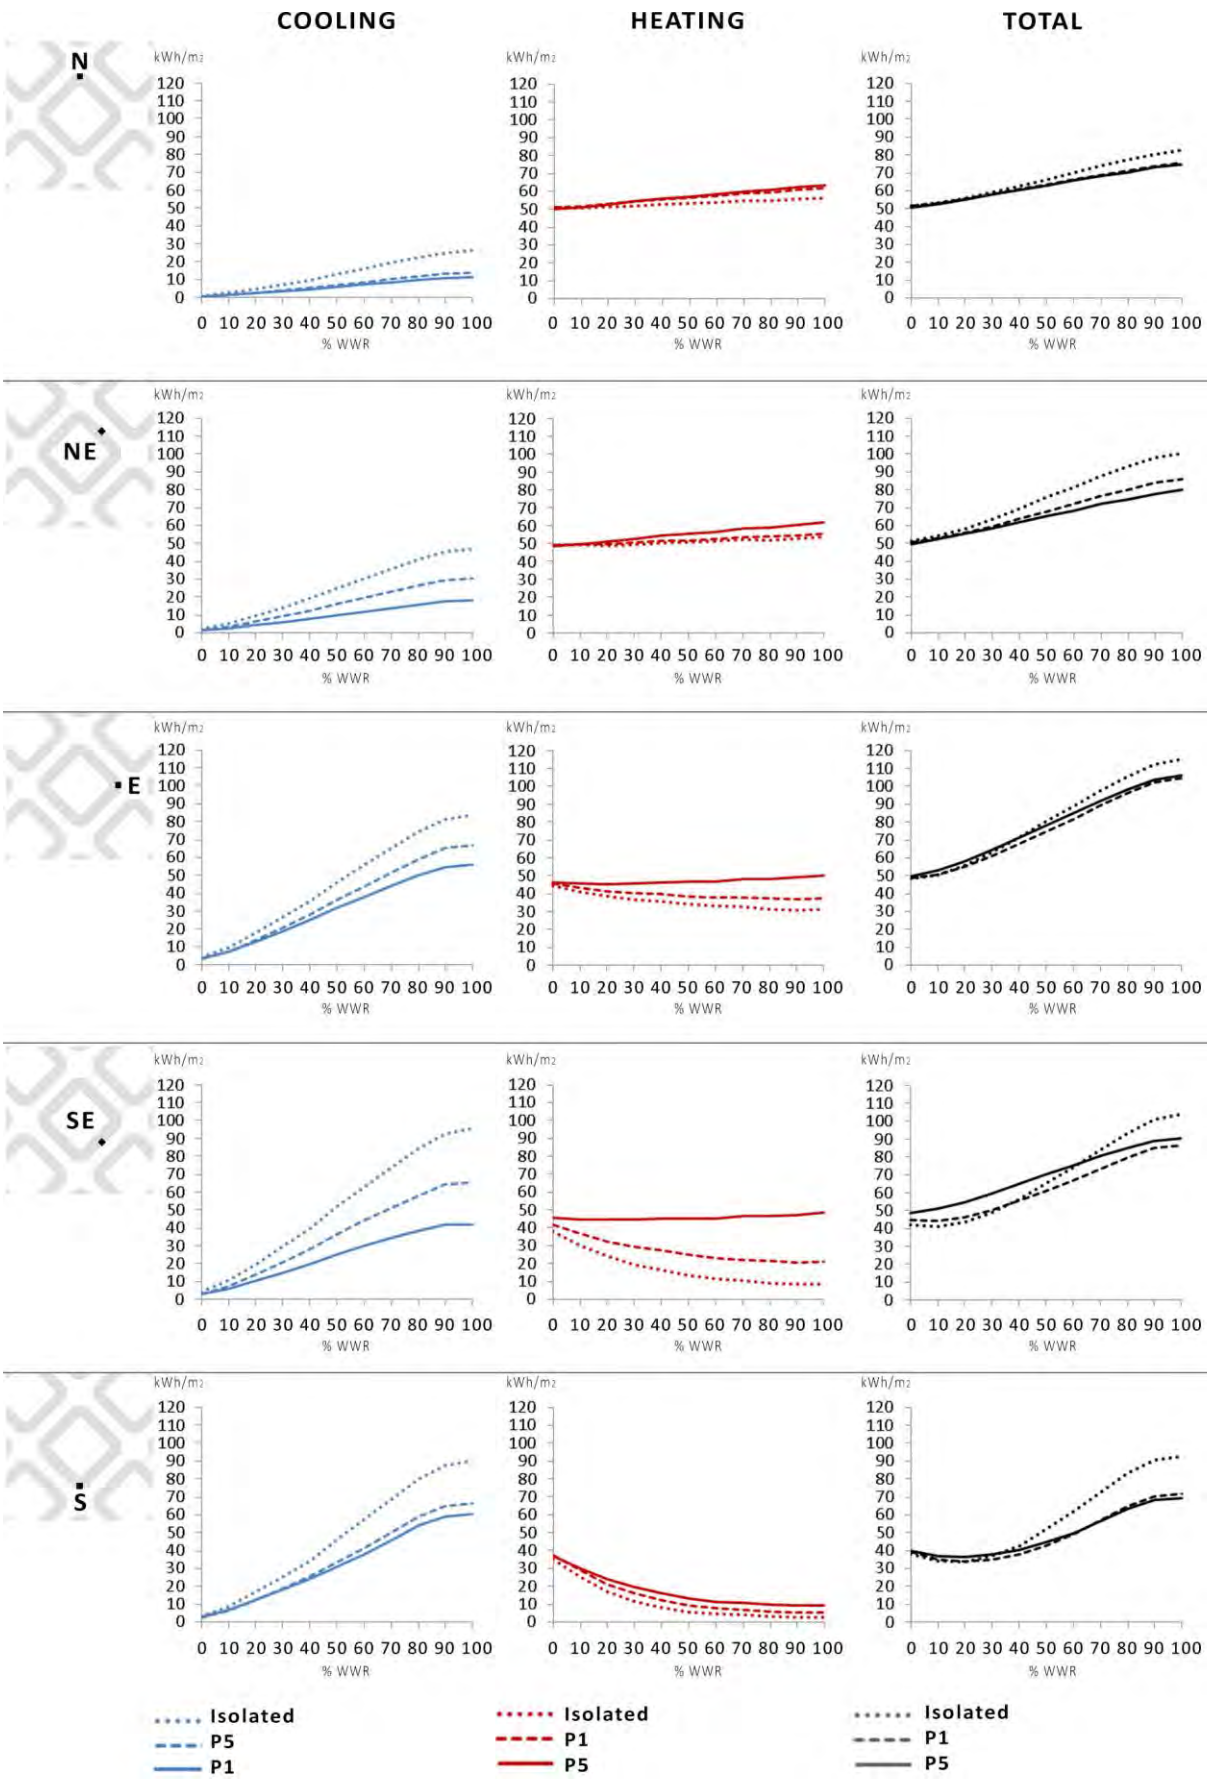

Figure 3. Air conditioning demands for an isolated and an urban block at levels P1 and P5.

Figure 3 shows that the increase in the opening size results in an almost linear rise in cooling requirements for all the analysed cases. Since cooling needs are mainly driven by radiation loads, the significance of this increase demand will depend not only on orientation but also on the degree of obstruction. Consequently, for the same orientation, the higher the floor level is, the more noticeable the increases in cooling demands are computed as openings enlarge. Changes in cooling demand due to higher WWR may be significant in both relative and absolute terms, increasing energy needs between 11 to 64 kWh/m^{2}year (in N-L1 and E/W-L5 cases, respectively).

As for heating demand, the enlarging of the glazed surface has uneven effects on energy requirements depending on the orientation and the degree of obstruction. On one hand, a decrease in heating needs is observed for south facing spaces and the less obstructed ones facing SE/SW and E/W orientations. This reduction in energy demand is explained by the fact that, for these locations, solar gains exceed conduction losses. Due to this effect, heating demand is reduced between 8 and 32 kWh/m^{2}year (in E-L5 and S-L5 cases respectively). On the other hand, the growth of the window size is associated to a slight increase in heating requirements for the rest of orientations regardless the height.

Regarding total air-conditioning demands, the parametric increase from 0 to 100% of WWR is linked in general terms to a rise in energy needs (ranging from a 1,5 to a 2,1 factor for N-L1 and E/W-L2 cases respectively). However, it is worthy to differentiate two particular situations in this regard. On one hand, for all N, NE, NW, E and W cases, the bigger the window is, the higher total demand is computed, reaching the minimum total demand for a 0% WWR. On the other, for S, SE and SW orientations the minimum air conditioning demand is reached between the 30% and 10% WWR.

Optimization of WWR to minimise total air-conditioning demand

In this subsection, the WWR optimization based on the minimisation of the total air-conditioning demand (T_{min}) is discussed. In this regard, two different scenarios have been assessed and graphically represented (Figure 4 and 5).

First, the “optimum WWR” for each case is determined as the glazing ratio linked to the minimum total air conditioning demand (T_{min}), without any further constraints on the window size. Though in this scenario lightning requirements may not always be fulfilled, it constitutes a conceptual approach on the thermal impact of the window size worthwhile to analyse. Results for this optimisation case are depicted in the elevation of Figure 4. Under this approach, windows would be present only in south façades and in the higher floors of southeast/southwest ones. These results indicate that, for the study case, the presence of glazing surfaces only has a positive thermal impact for S, SE and SW orientations and under highly-unobstructed conditions.

Second, the “optimum WWR” is defined as the maximum window size that does not lead to a “significant increase” in demand compared with T_{min}, being WWR≥ 10% in any case. For the present study, a “significant increase” has been defined as an increment of 10% of T_{min}. Block elevations based on these criteria are depicted in Figure 5. Urban façade design resulting from this thermal optimisation is characterised by a non-uniform layout. Differences in WWR glazing ratios are detectable between orientations. Additionally, for the more obstructed façades (SE, SW, NE, NW), they are also present in height, reflection of the link between obstruction and the window net energy performance.

It is worth-mentioned that the maximum glazing ratio obtained for this scenario (30%) is similar to the WWR average found by the authors in their ongoing research about fenestration in the *Eixample*. A possible explanation for this parallelism could be the existence of a non-explicit knowledge on the part of designers about certain façade configurations which pose a good compromise between thermal and lighting performance for this climate and urban context.

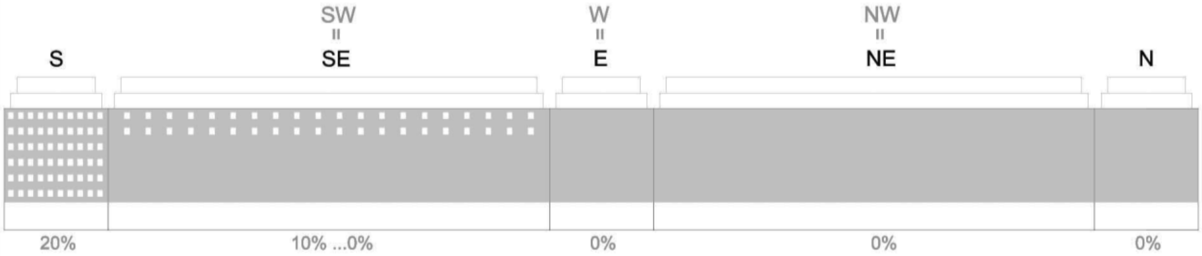

Figure 4. Elevation with WWR associated to the minimum air-conditioning demand.

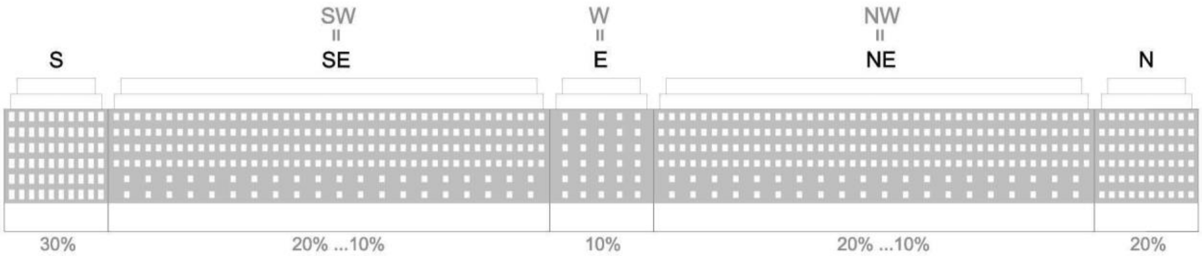

Figure 5. Elevation with WWR increasing by less than a 10% the minimum air-conditioning demand.

Conclusions

In this paper, the impact of WWR on air-conditioning demands has been discussed from an urban perspective. Results indicate that, for the climate of Barcelona, only the windows with a south component (S, SE, SW) on highly unobstructed contexts present a net positive effect from a thermal point of view. It has been shown that, for the urban tissue of the *Eixample*, WWR increases beyond a 30% always result in rises in total air-conditioning demands, regardless orientation and degree of obstruction.

In this work, a discussion on the possibilities of optimizing WWR to minimize air conditioning needs has been also carried out for the *Eixample* case. To illustrate conclusions on this point, a schematic view about a thermally optimised urban landscape of the *Eixample* has been included (Figure 6). The urban layout of the tissue is highlighted as one influencing factor regarding the obtained optimum glazing ratio. Consequently, façade design resulting from a thermal-based WWR optimisation differs among orientations. In addition to this, the optimum opening size from a thermal point of view grows in height (the higher the floor, the bigger the window) for the more obstructed façades.

The complexity of energy exchanges taking place through the building façade makes difficult for architects to understand the consequences of its design. Results of this work provide insights about thermal implications associated to changes in the WWR, an aspect which is present from an early stage of design. Findings on this paper may also contribute to a better understanding of the role of façade design regarding the thermal behavior of urban tissues.

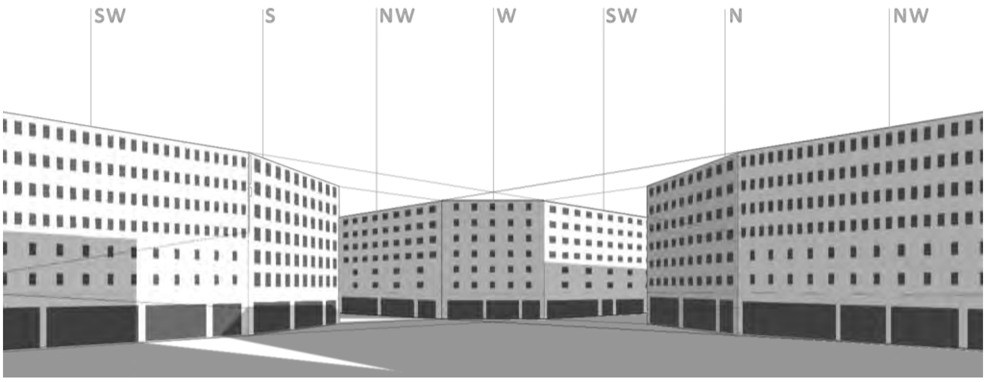

Figure 6. Urban landscape of *Eixample* with WWR which minimises air conditioning demands.

Abstract: *Jaalis* are perforated screens which were used as window treatments, predominantly found in Indian, Indo-Islamic and Islamic architecture. Historically, they have been extensively adopted in regions characterized by high solar radiation, to provide ample shade and privacy. In recent years, these screens are introduced for their aesthetical character. In a building envelope, glazing accounts for the major heat transfer into the built space, thereby increasing the cooling load. Appropriate shading of the glazed façade area, through *Jaali* screens serves as an effective strategy by reducing the high intensity radiation, thereby can cut down the energy loads considerably. The study aims at evaluating the performance of external *Jaali* screens as window treatments, through the design of a school in 'Warm & Humid climate' of Tiruchirappalli, Tamilnadu, India. Various permutations and combinations were used in devising optimum screen configurations for different orientations of the envelope, which ensures adequate shading when the intensity of radiation is above the shading line, such that the heat ingress into the building is obstructed. The shading criterion is adopted as per adaptive comfort model in ASHRAE 55. These are further tested using Ecotect and Radiance simulation tools for calculating shading and for their performance on Day lighting.

Keywords: External *Jaali* Screens, Solar radiation, Optimum Screen Geometry, Solar Shading, Day lighting.

Introduction

The windows account for the greatest amounts of heat entering the building and therefore shading them, offers the greatest protection" [Olgay, 1963, p72]. Solar shading affects the energy use in a building by reducing solar gains and modifying thermal losses through windows. Shading devices also influence day lighting levels in a room and the view to the exterior(Ayesha Batool, December, 2014). Shades are divided into four categories, such as shades, blinds, screens and switchable glazing(Dubois, 1997).

Shading of buildings with respect to both energy use and comfort is a complicated task. Fortunately, there are many studies that had been carried out in analysing the effect of shading devices on energy use and day lighting(Dubois, 1997). Solar heat gain reduction is of primary concern, to improve thermal comfort and subsequently reduce energy demand, thereby providing comfort to occupants in warm weather (Boake, 2014).

*Jaali*screens are perforated screens which are used as window treatments in traditional buildings(Kamal). Historically, these screens have been extensively adopted in regions characterised by high solar radiation, to provide ample shade and privacy. *Jaali*s are one of the architectural elements used from history which contributes to the user comfort. *Jaali* manages to cut down on direct sun and thereby the heat ingress. It also allows movement of air for cross breeze and ventilation.

Several studies have discussed the use of external *Jaali* screens for achieving indoor thermal comfort; whereas there is very sparse literature that addresses these screens quantitatively. A better understanding of the effect of screen geometry on energy saving can be used for developing new efficient designs that suit the harsh conditions (A. Sherif, 2012).

Rationale of the Study

The study focuses on breakdown of screen geometry with respect to the Altitude, Azimuth of the sun's position and the Global Horizontal Radiation (GHR).The criteria for shading needs are addressed for a classroom in a school building located atTiruchirapalli, India. Appropriate criteria for shading needs are devised byvarious geometries of the screen for shading the glazed fenestration for major orientations. The study limits only to the optimum screen geometry, where the material of the screen and type of glazing are kept constants. The study concerns only on the thermal and lighting performance of *Jaali*screens, while the ventilation strategy of the screen is not considered.

Climate Interpretation

Tiruchirappalli has a Warm & Humid climate with hot summers and dry winters. Temperature in this region generally ranges between 21°C to 38°C and is rarely below 19°C or above 40°C (Weather Spark).The bioclimatic chart is plotted for the average relative humidity with respect to average dry bulb temperature (NREL,EnergyPlus). From the chart, it is clear that natural ventilation is required throughout the year and the shading devices promote the air movement while obstructing the direct radiation from sun.

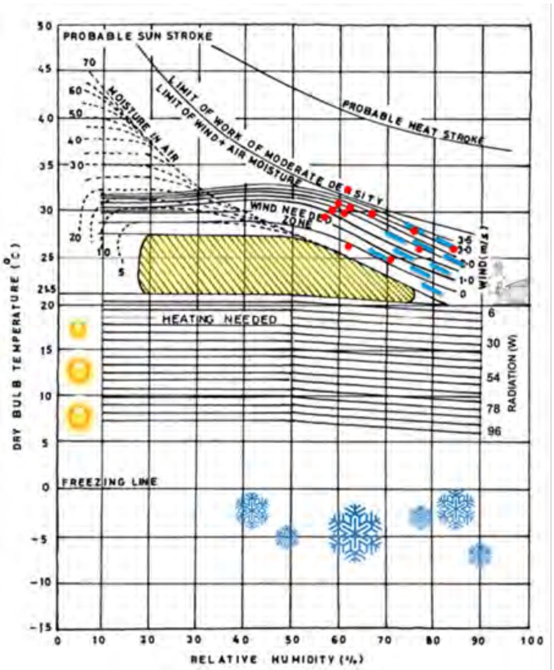

Figure 1.Bioclimatic chart of Tiruchirapalli

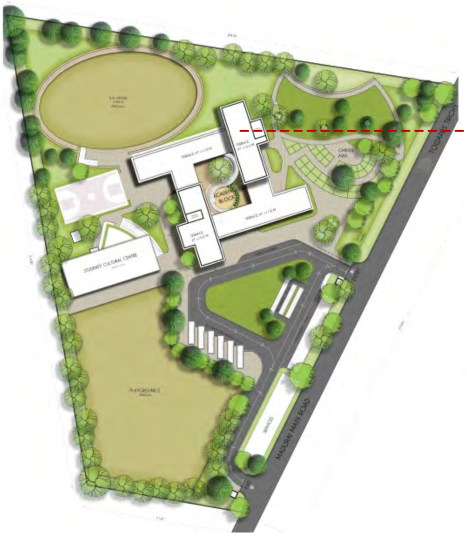
Design Considerations

The residential school building is located at a site, which is trapezoidal in shape, longer axis oriented along East – West, widespread to an area of 7.9 acres. An academic block of 1985 sq.m area is proposed along-17.5° North-South, which serves as the optimum orientation, due to the lesser incident radiation (Wh/m²) received on the surfaces (NREL,EnergyPlus).The form is evolved such that it addresses the major design consideration of shading, being mutually shaded during majority of the time of a year, with spaces organised along a central courtyard.



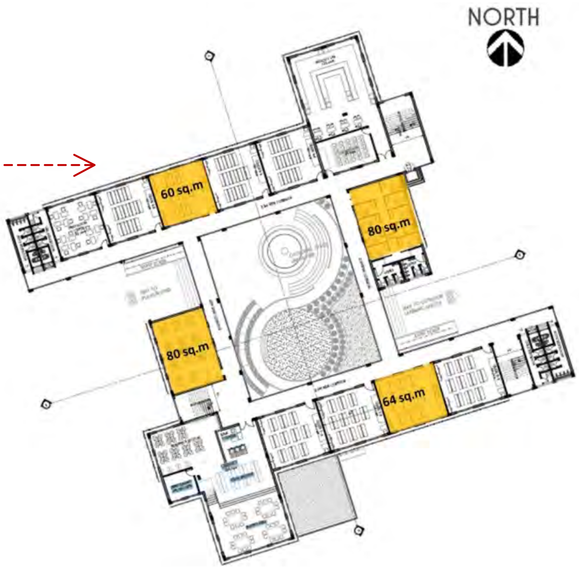


Figure 2.Site Plan showing the location of the Academic Block (Left)
Figure 3.Academic Block plan showing the classrooms (Right)

The academic block in Fig.3 shows four different classroom spaces in all four major orientations (North, South East & West), which is considered as sample for evaluation of shading and lighting for the *Jaali*screen configurations. The consideration taken for simulation using the Autodesk Ecotect simulation tool were, reflectivity of walls, ceiling and floor as 0.7, 0.8, 0.6 respectively, the work plane is kept constant at +0.6m from floor level, depth of the *Jaali*screen was kept constant at 5cm and the module sizes were devised for uniform size of (0.5 x 0.5) m and the material of *Jaali* screens was Glass fibre reinforced concrete (U value-0.0374 BTU/ hr ft² °F).

Methodology

Shading Analysis

Shading obstructs the direct beam radiation exposure thereby cutting down the heat ingress into buildings. In order to determine a baseline above which shading is required, ASHRAE adaptive comfort model is studied which recommends for shading when the Global Horizontal Radiation (GHR) is greater than 315.5 Wh/m² (Climate Consultant 6.0).

Hence, hourly average Global Horizontal Radiation throughout the year is been tabulated as shown in Table 1 and the GHR over 315.5 Wh/m² is highlighted and is plotted over the Sun path diagram to critically shade the periods exposed to high intensity of radiation. The aim of the screen geometry is to cut down this high intense radiation and shade the glazing adequately in major orientations of the design.

Table 1. Hourly average Global Horizontal Radiation of sun with Altitude and Azimuth angle

The *Jaali* screen configuration varies for different altitude and azimuth of sun position at various times of the year. Thus, the altitude and azimuth for every hour was optimized and respective Horizontal Shading Angles (HSA) and Vertical Shading Angles (VSA) were tabulated. The required HSA and VSA highlighted in the sun path diagram shows that the critical area is shaded as shown in fig.4. The screen geometry is now devised for the respective HSA and VSA to achieve optimum shading.The depth of the screen was kept constant at 5cm and the module sizes were devised for uniform size of (0.5 x 0.5) m.

Results

Shading calculation

The simulation results for shading the major orientations with *Jaali* screens are shown as follows,

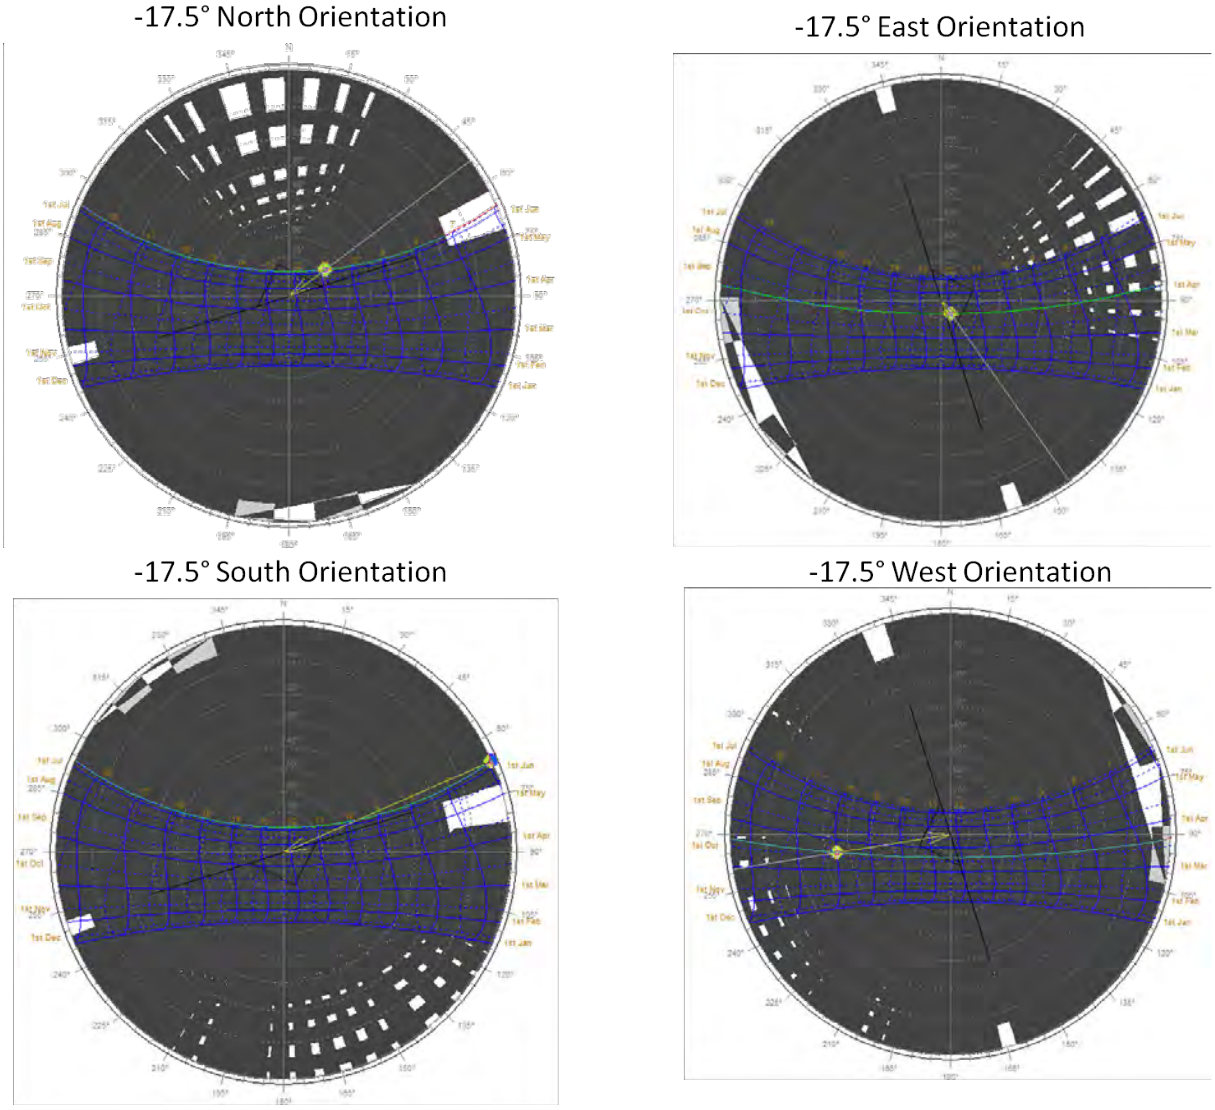

Figure 9. Shading Calculation of the screen for four major Orientations

Lighting Evaluation

Minimum Daylight requirements as per ECBC is: For a non-residential building having less than 3 stories above the ground shall have a minimum of 45% of its floor area exposed to daylight in range of 100 – 2,000 lux for at least 90% of the year (USAID Eco III Project, Energy Conservation Building Code 2017 - User Guide, Bureau of Energy Efficiency). The design is evaluated to meet the ECBC daylight requirements.

The evaluation is done for 15th of every month of a year in two time intervals (i.e., 10.00 am and 3.00 pm). The maximum, minimum and average illuminance for every month is tabulated as shown in Table2.*(UDI is defined as the annual occurrence of daylight between* ***100 lux to 2,000*** *lux on a work plane. This daylight is* ***most useful to occupants****, glarefree and when available, eliminates the need for artificial lighting.)*

The worst case scenario is taken during the time with highest sky cover, during which thedaylight availability is considerably reduced. For the climate of Trichy, the worst case scenarios occur during the month of october which has highest sky cover up to 68% (Climate Consultant). The values are simulated for Oct 12 & 13 which experiences 100% sky cover between 9am to 5pm.

Table 3.Illuminance for Worst case Scenarios in a year

WORST CASE SCENARIO					
ORIENTATION		NORTH JALI	EAST JALI	SOUTH JALI	WEST JALI
TIME		OCT- 12, 1.00PM	OCT 13, 1.00PM	OCT 13, 12.00 NOON	OCT 12, 10.00AM
ILLUMINANCE	AVERAGE	366.42	270.04	333.91	333.91
	MINIMUM	141.74	139.7	148.19	148.19
	MAXIMUM	1285.96	1148.19	1230.89	1230.89

Observations and Conclusion

Shading calculation for optimum screen configuration for all four major orientations in fig.9 shows that the windows are shaded throughout the year for the recommended Global Horizontal Radiation plotted on the sun path diagram.

These *Jaali*screens then are tested for lighting through analysis for different months on all four major orientations. The results in Table 2 show that all the tabulated values lie within the range of 100-2000lux which is considered as the useful daylight, glare free while eliminating the need for artificial lighting. In addition to the monthly average lighting analysis, the worst case scenario of a year is taken into consideration. Table 3 shows that all four orientations in spite of being shaded with *Jaali* screens receive the desired lighting between 100-2000lux as per ECBC recommendation. Hence, throughout the year the classroom spaces receive continuous daylight while the windows are being sensibly shaded with *Jaali* screens.

Open windows for natural ventilation and outdoor noise reduction in tropical climates

Abstract: 'Real' open windows for buildings in tropical climates were studied. It focused on the window degree of openings and window orientation toward the noise source. The window type to be tested was top-hung shutter type only, based on multitasking duty between permitting airflow and noise blockage. The top-hung open window with a uPVC frame was tested of 3 orientations, i.e. perpendicular, oblique 60°, and 90°. The degree of openings was tested on 0° (closed), 5°, and 10°. Laboratory tests according to ASTM E90-09 were conducted to determine transmission loss (TL) & ASTM E1332-90 was referred to calculate the outdoor-indoor transmission class (OITC). Later, finite element analysis using COMSOL 5.0 was conducted to study the sound contour developed around the models. The study revealed that window orientation has little effects of noise reduction. Here, a 'real' open window is still not capable of blocking noise into the living spaces. However, when the open window was closed, perpendicular orientation offered higher OITC compared to the oblique ones. Thus, a perpendicular orientation is more recommended to reduce noise.

Keywords: natural ventilation, tropical climate, open window, top-hung window, OITC

Introduction

Buildings in tropical climates encounter totally contradictory requirements between using lightweight materials and open envelopes for natural cooling and using weighty materials for environmental noise blockage. 'Real' open windows were studied here. The term real open window is used to separate it from a partially open double layered window suggested for ventilation and noise abatement (Ford and Kerry, 1973 and Burrati 2002 & 2006), but impractical for tropical climates. In a tropical warm-humid climate, a passive cooling by means of open windows shall have an open area of at least 5% of the ventilated floor area (SNI 03-6572-2001). As an example, a 15 sqm floor area will need 0.75 sqm of openings. With a partially open doubled layered window with say a maximum gap of 0.2 m, the room will need window as wide as 3.75 m, which is considered impractical for 15 sqm floor area only.

The existence of real open windows where the use of mechanical ventilation is mostly at night time due to energy saving issue and even for public buildings with the energy savings in mind is significant. A real open window that may conquer noise intrusion is a later issue. Openings placement on a wall will reduce the wall sound insulation property. As in general glass walls are thinner than masonry walls, the sound insulation property decreases accordingly (Quirt, 1981; Quirt 1982; Garg et al, 2011). Earlier studies have indicated that in warm temperature, laminated glass offered the best STC and TL contour compared to monolithic and tempered glass. But the OITC was low due to a coincidence dip developed at 125 Hz (Mediastika et al, 2015; Mediastika et al, 2016a). In overall, the use of glass in a temperature warmer than the ASTM E90-09 was suggested to be slightly thicker. In warm temperature, the STC and OITC of glass are 1 to 2 levels lower (Mediastika et al, 2015; Mediastika et al, 2016a).

Besides the specific glazing type of windows that will work for warm temperature, an earlier study has also recommended a particular framing material for conquering noise intrusion by an open window. When the open window was closed, a uPVC frame offered the best insulation. A laboratory test of timber, Aluminium, and uPVC proved that insignificant sound insulation was gained when the windows were opened (Mediastika et al, 2016b). In the study reported here, the orientations of glass windows to the noise source were tested in the laboratory of 1 to 1 scale, analysed, and verified using COMSOL 5.0 Multiphysics regarding the sound contour developed around the specimen.

Methods

The study reported here is a series of empirical research, some have been reported and published, i.e. study on insulation properties of several glass types and study on the insulation properties of framing material for glass windows. The studies were conducted comprehensively using the following methods.

- Selection of glass types to be tested based on glass types commonly used for building facades in Indonesia (Anonymous, 2015). The tested specimens were monolithic, tempered and laminated. They were tested using ASTM E90-09 with a specific condition was applied based on Annex.3 on the use of the composite wall system (Figure 1). Equipment used for testing was Bruel & Kjaer 2- channel building acoustic system consisting of power amplifier type 2734 and 4292 omnidirectional loudspeakers as the sound source, 2 pieces of type 4189 omnidirectional microphones as the sound sensor, and 2-channel handheld analyzer type 2270 as the main instrument data processor. The microphones were calibrated using type 4231 prior to the testing stage. The room temperature was set at 27°C to 32°C as a replica of the average daily temperature of tropical climate (Feriadi & Wong, 2004; Hariyanto, 2005; Karyono, 2000). The first stage of glass testing showed that laminated glass types offered the best TL contour and STC, but not of the OITC due to a coincidence dip at 125 Hz.
- The next stage was to test frame materials suitable for openable windows and that are commonly used in Indonesia, which is timber, Aluminium, and uPVC. They were tested using ASTM E90-09 with a specific condition were applied based on Annex.3 with laboratory equipment as were used during the first testing stage. The second testing stage concluded that with rubber strips and sealant, a uPVC frame offered the best insulation for both fix and open windows when the open window was closed.
- The third testing stage reported here was to study the orientations of glass window toward the noise. It is perpendicular, oblique 60° and oblique 90° (Figure 2). A particular glass window type; top-hung; was selected due to shutter position that may

block noise pathways. Glass type, glass dimension, and frame material were the fix variables, which is monolithic glass, 10 mm thickness, 800 mm x 1200 mm, and uPVC frame (Figure 2). With the early testing stages have indicated the best insulation offered by a glass type and a frame material, glass type and frame material used at this stage were based only on resources limitation and the ease of installation. The testing method and equipment employed at this stage was similar to those of the earlier stages. The temperature and relative humidity (RH) during the testing period were 25°-26°C and 80% - 90%.

- In this study, the orientations of the open windows were assigned as the variable to be tested, but the window style was determined as a fixed variable. It was a top-hung open window style. The top hung style was selected based on the capability to permit ventilation and the possibility of noise blockage by the shutter position (De Salis, et al, 2002, Figure 2). Gao and Lee (2010) determined that the top-hung window type was the worst in natural ventilation compared to end-slider and side-hung. But these 3 types were chosen by Gao and Lee as the possible types for natural ventilation only. The lowest ventilation rate by the top- hung window was caused by the shutter position that blocked the airflow. However, still, a top-hung window was capable of supplying natural ventilation (Coley, 2008) when be compared to the 'non-real' open window (Ford and Kerry, 1973 and Burrati 2002 & 2006). Another window type with similar shutter position to top-hung, such as bottom-hung was not tested due to the limited resources. Besides, the bottom-hung window is rarely used in Indonesia caused by the less accessible handle and latch.
- The top-hung window was tested at 3 degrees of openings, i.e. 0° (closed), 5°, and 10° (Figure 3 and 4). The closed condition was tested to study whether the gap between frame and the shutter has an effect on noise intrusion due to the window position. The 10°was selected as the maximum degree of opening for safety reason and ease of people movement along the corridor or space by the window.
- The OITCs were calculated from the TL of 1/3 octave band frequency according to ASTM E1332-90.
- The test specimen was then modelled in a finite element analysis using COMSOL 5.0 Multiphysics to study the sound contour around the specimen to confirm the finding of the laboratory test.

Findings and Discussion

A series of laboratory test has been conducted to see the effect of a top-hung open window in blocking noise. The result of the laboratory test is compiled in Table 1. When the open windows were closed (open 0°), the OITC of perpendicular orientation were higher than the oblique ones. But when they were opened, the OITC values were similar regardless orientations, either perpendicular or oblique and regardless degrees of obliqueness. These findings strengthen earlier studies that larger degree of openings permits noise intrusion easier (De Salis, et al, 2002). Both the oblique that seemed to have a larger open area and the perpendicular that seemed to have a smaller open area due to the shutter positioned parallel to noise performed similar OITC.

Later, the laboratory findings, which showed that insulation values of either oblique 60 (or 90 (were similar were confirmed using finite element simulation to see the sound contours developed around the openings. Figure 5 shows that both orientation results in similar sound contour, sound dispersion, and sound levels. It means that either 60° or 90° obliques did not offer different insulation values to noise. It is more interesting to study the sound transmission loss (TL) contour of the specimen shown in Figure 6. Here, all closed open windows drawn similar contours except the oblique, which indicated a coincidence dip at 80 Hz. It was predicted not due to the gap position between the frame and the shutter, but due more to the presence of an angle of the oblique wall. However, the finite element analysis showed that the sound dispersion developed around the openings is similar, means that the wall's angle did not affect the sound contours. One thing should be remembered, simulation by using finite element does not consider the sound frequency. It is only the sound intensity that is taken into account. Thus, the condition of coincidence dip was not represented in the simulation. A further test conducted in a laboratory with larger dimension to accommodate low sound frequencies pathways, is significant to confirm this finding.

Conclusion and recommendation

The laboratory test and the computational simulation were in good agreement. The laboratory test showed a 'real' open window of a top-hung style offered OITC as low as 5, regardless window orientations. It was supported by the COMSOL simulation that showed TL contours developed around the model were of high noise levels. The offered OITC value is considered too small to reduce environmental noise in the residential area, which might reach up to 75 dB (Iswar, 2005). But when the open window was closed, perpendicular orientation resulted in higher OITC compared to the oblique ones. Five degrees of openings resulted in OITC of roughly 2 points higher than the 10°. For natural ventilation purposes in tropical climates, 10° of openings may be preferable. But the users should be aware of the low OITC offered by 10° of openings. In overall, a 'real' open window positioned perpendicular to noise source is suggested to conquer noise whenever it is open or closed. A 'real' open window is still incapable of providing significant noise reduction whatsoever.

Window use: Potential and challenge to more energy-efficient residential buildings in hot-humid climates

Pimolsiri Prajongsan[1]

[1] Faculty of Architecture, Silpakorn University, Bangkok, Thailand,
prajongsan_p@silpakorn.edu

Abstract: Window use is a challenging issue for mixed-mode residential buildings to achieve energy efficiency. According to 216 residents from 15 condominiums in Bangkok, more than 75% of the respondents operate a/c in their bedrooms during nighttime, regardless of external climatic conditions. In this study, four modes of window use i.e. *no ventilation, all-day ventilation, day-time ventilation and evening-time ventilation* and their effect on a bedroom's cooling energy use were investigated using the EnergyPlus function in DesignBuilder version 5.0.1.024. The way windows are used was found to have an effect on the bedroom's cooling energy use. Airflow rate and indoor-outdoor temperature difference were key parameters to determine such effect. In this particular case, the bedroom with *evening-time ventilation* had the lowest annual cooling energy, while that with *day-time ventilation* had the highest. The differences of cooling energy use could reach 13.0-17.6kWh per year, depending on the bedroom orientation. These results indicate that residents' behavior is crucial for determining the successfulness of mixed-mode residential buildings to achieve energy efficiency and window use could be employed as a promising post-occupancy strategy for reducing the buildings' electricity consumption due to cooling systems.

Keywords: window use, post-occupancy, mixed-mode ventilation, residential buildings, hot-humid climates

Introduction

More than 2,300 residential buildings, or '*condominiums',* which accumulate 340,000 residential units have been built in Bangkok metropolitan area since the last ten years (Bangkok metropolitan administration, 2015). These condominiums are mostly the change-over type of mixed-mode buildings - natural ventilation and cooling systems are employed in the same space, but at different times. Operable window(s) and split-type air conditioner(s) are installed in each residential units and they are controlled by the residents.

For a naturally ventilated residential building in hot-humid climates, architectural characteristic is a significant parameter to determine the success of the building in employing comfort ventilation as a passive tool to maximize its resident comfort. To achieve this, architects are suggested to concern on key issues including spacing among buildings, figure and layout of a building regarding to its environment as well as the building's opening design (Prianto et al., 2002; Liu et al., 2014; Zhou et al., 2014). On the contrary, not only architectural characteristic, but also occupants' behavior is crucial for assuring the successfulness of a mixed-mode building in terms of its energy efficiency. This is particularly true for window use as it is the most uncertain and less predictable parameter that affects a building's energy use due to cooling system (Nicol et al., 2004; Rijal et al., 2007; Ackerly et al., 2011; Liping et al., 2015).

Window use is found to depend on the occupants' perception and expectation of comfort, which are mainly related to outdoor climatic condition, indoor thermal condition as well as time of the day (Yun et al., 2008; Andersen et al., 2009; Huang et al., 2014). In this study, the residents' behavior on window use and its effect on a building's cooling energy use were investigated. Window use was hypothesized to have an effect on a building's indoor air temperature, heat balance and, thus cooling energy use, which in turn could be helpful for a mixed-mode residential building to achieve more energy efficiency.

Methodology

In this study, typical characteristics of high-rise condominiums built in Bangkok metropolitan area since the last 10 years were surveyed. Then the residents' behavior on air-conditioner (a/c) and window use was studied using questionnaire and short-interview. Finally, such residents' behavior was investigated in terms of its effect on a building's energy use for air-conditioning systems using EnergyPlus 8.5 built in DesignBuilder version 5.0.1.024.

High-rise condominiums and the residents

In 2016, the architectural characteristics of 72 high-rise condominiums those situated within 500m from Bangkok mass rapid transit stations were surveyed. The condominiums were middle to upper-middle class, which were developed by six private developers who continually launch high-rise condominium projects since the last 10 years. It was found that all the condominiums are double-loaded i.e. a building with an internal corridor that provides access to units on both sides. Most of the residential units are single bedrooms with floor area ranging from 26m^2 to 50m^2 and almost all the units have single-sided ventilation. In this study, one of the three layouts of single bedroom units commonly found from the survey was employed as a studied building (Figure 1).

The behavior of the residents in these condominiums were also investigated. There were 216 questionnaires collected from the residents of single bedroom units from 15 condominiums. It was found that most of the units are occupied by 1-2 persons (81%, N=216). During weekdays, the units are occupied mostly in the evening and at night (18:00-22:00hrs in the living room and 22:00-7:00hrs on the next day in the bedroom), while most of the living rooms are occupied all day during weekends. In terms of a/c use, more than 98% and 89% (N=216) of the respondents installed a/c in their bedrooms and living rooms, respectively. Most of them operate a/c in their bedrooms at night, either in summer or winter season. Only a small number of the respondents use their windows on weekdays and weekends (35.6% and 38%, N=216, respectively). However, these respondents use their windows in different ways - some respondents (9.1%, N=22) leave their windows open all-day (7:00-20:00hrs) during weekdays when they do not occupy the unit to use incoming fresh air for reducing undesired odour and humidity found indoor, while the others (40.9%, N=22) open their windows during evening-time to flush out the hot air accumulated indoor before operating a/c.

Simulation setup

A studied building was formulated as a 20-floors building (WxLxH=16mx70mx60m), according to typical characteristics of high-rise condominium found from the survey (Figure 1). The building was a double-loaded corridor type with single bedroom units situated on both sides on every floor. A single-sided ventilated unit on floor-10 was chosen as a studied unit and its bedroom (11.75 m^2) was used here for investigating the effect of different window uses on the bedroom's cooling energy. The building external wall was precast concrete (U-factor with air film = 4.565Wm^{-2}.K) with 2.88m^2 fixed tempered laminate glazing

(12mm-thick, U-factor with air film=6.108$Wm^{-2}.K$, SHGC=0.559) and operable window (a top-hung window with maximum operable area of approximately 20% i.e. about 0.14m^2).

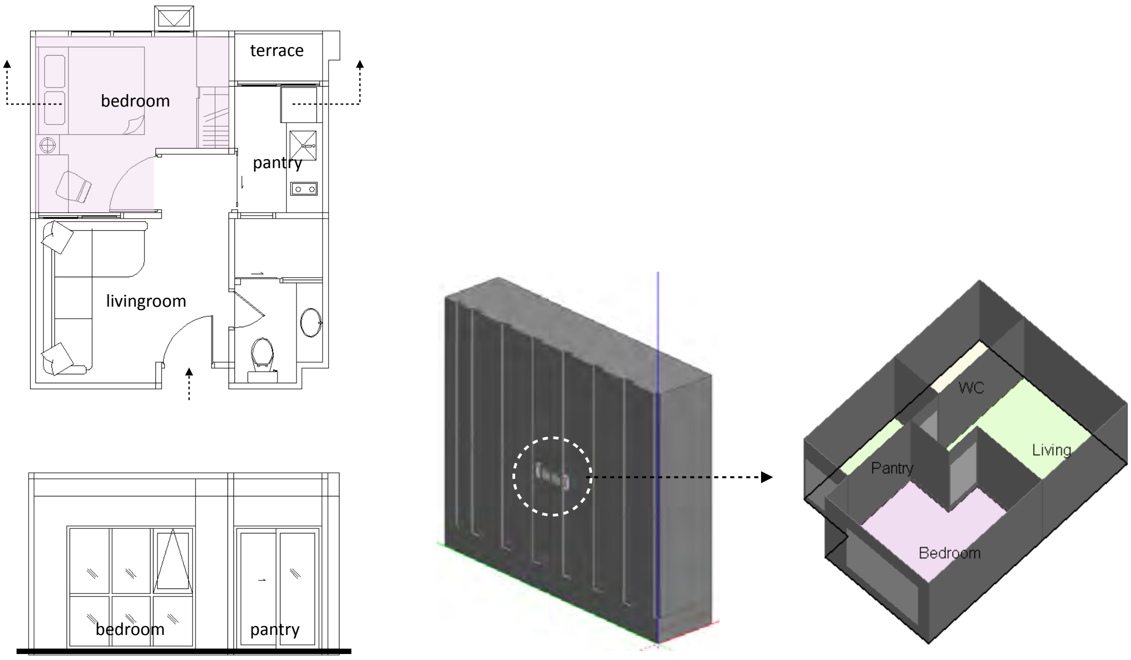

Figure 1. The studied unit: (left) layout and elevation towards the external wall, (middle) the location of the studied unit in the studied building and (right) the simulated studied unit.

In order to investigate the effect of window use on the bedroom's cooling energy use, a/c in the bedroom was assumed, according to the survey, to be operated daily during 22:00-7:00hrs on the next day. The doors between the bedroom, the living room, the pantry and the terrace were assumed to be open during the time when the window was open. Four modes of window use in this study involve:

- Mode A (*no ventilation*): The window is closed at all time.
- Mode B (*all-day ventilation*): The window is open all day (7:00-22:00hrs.).
- Mode C (*day-time ventilation*): The window is open during daytime (7:00-17:00hrs.).
- Mode D (*evening-time ventilation*): The window is open during evening-time (17:00-22:00hrs).

Default Bangkok weather data was employed throughout the study. The a/c set-point temperature was assumed as 26 degree Celsius. External infiltration was assumed as '*medium crack*' when a/c was off and mechanical ventilation was assumed as 0.56 $l.s^{-1}.m^{-2}$ when a/c was on, according to the minimum requirement for fresh air by Thailand Building code. Internal heat gains included occupancy (90W/person, 2 persons were assumed in the bedroom, occupied period was during 22:00-7:00hrs on the next day); and lighting (2.6 $W.m^{-2}$, during occupied period). Wind pressure coefficient (C_p) used in this study was calculated using the external CFD function of DesignBuilder software.

In total, there were 48 simulations performed in this study. These involve two main stages of the study: i) 32 simulations for investigating the effect of four different window uses on indoor air temperature and external heat gain of the studied bedrooms facing to four main orientations i.e. South, North, East and West during two period i.e. summer typical day (in May) and winter typical day (in November); and ii) 16 simulations for investigating the effect of four different window uses on the annual cooling energy use of the four-oriented bedrooms.

Results and discussions

According to the simulations, the effect of four window uses on the bedroom’s air temperature and heat balance due to external air during typical summer and winter day as well as the effect on the bedrooms’ annual cooling energy use were revealed.

Effect of window uses on indoor air temperature

Air temperatures in the four-oriented bedrooms with four window uses were investigated. Figure 2 illustrates the results of hourly air temperature (T_a) in the bedrooms on the chosen summer and winter typical day against the hourly dry-bulb temperature (T_{out}).

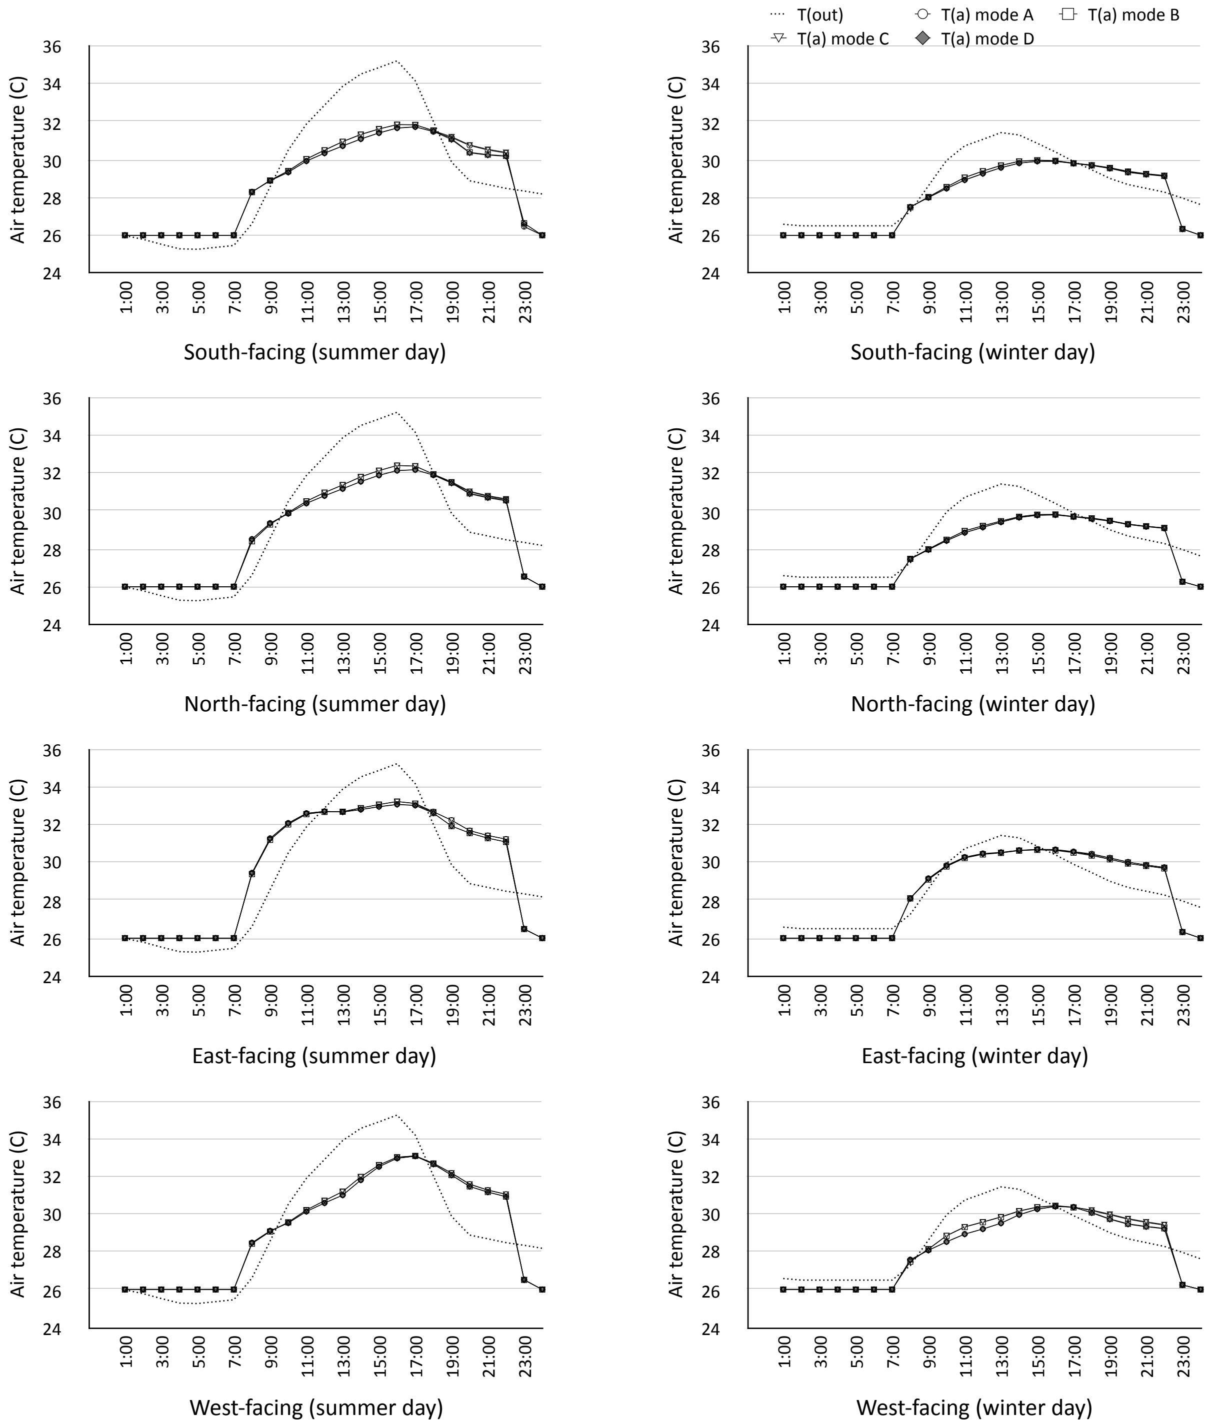

Figure 2: Hourly air temperature (T_a) in the studied bedroom with four modes of window use.

Indoor air temperature (T_a) in the bedrooms was found depending greatly on the rooms' orientation regarding to the sun path. Except for a/c period, T_a in South-, North- and West-facing bedrooms with different window uses all started to rise with the increase of T_{out}, reaching its maximum during 15:00-17:00hrs on the summer day and 14:00-16:00hrs on the winter day. Then it begun to gradually drop in the evening. Differently, T_a in East-facing bedrooms started to rise rapidly after 7:00hrs and stayed stably high throughout the day. It was also found that T_{out} was lower than T_a for all cases in the evening i.e. 18:00-19:00hrs onwards on the summer day and 16:00-18:00hrs on the winter day.

Also, different window uses were found to have a slight effect on the bedroom T_a. At 22:00hrs before the a/c was about to start, T_a of all the bedrooms with '*evening-time ventilation*' and '*all-day ventilation*' were slightly lower than those of the bedrooms with '*no ventilation*' and '*day-time ventilation*', particularly on the summer day. This was because the incoming air with relatively lower temperature may flush out the hot air accumulated indoor and thus help reducing the bedroom T_a. Although the air temperature differences among these bedrooms with different window uses were small i.e. 0.1-0.2 degree Celsius, but the effect of window use on the bedroom T_a was revealed.

Effect of window uses on heat gain

External airflow rate and heat balance of the studied bedrooms with four modes of window use were investigated. Figure 3 illustrates the results of external airflow rate (Q) and heat balance due to external air (H) in South- and East-facing bedroom on the summer and winter day. It should be noted that the external airflow rate includes incoming air through the operable window due to wind and stack effect during window use, assumed air infiltration when a/c was off and assumed mechanical ventilation when a/c was on.

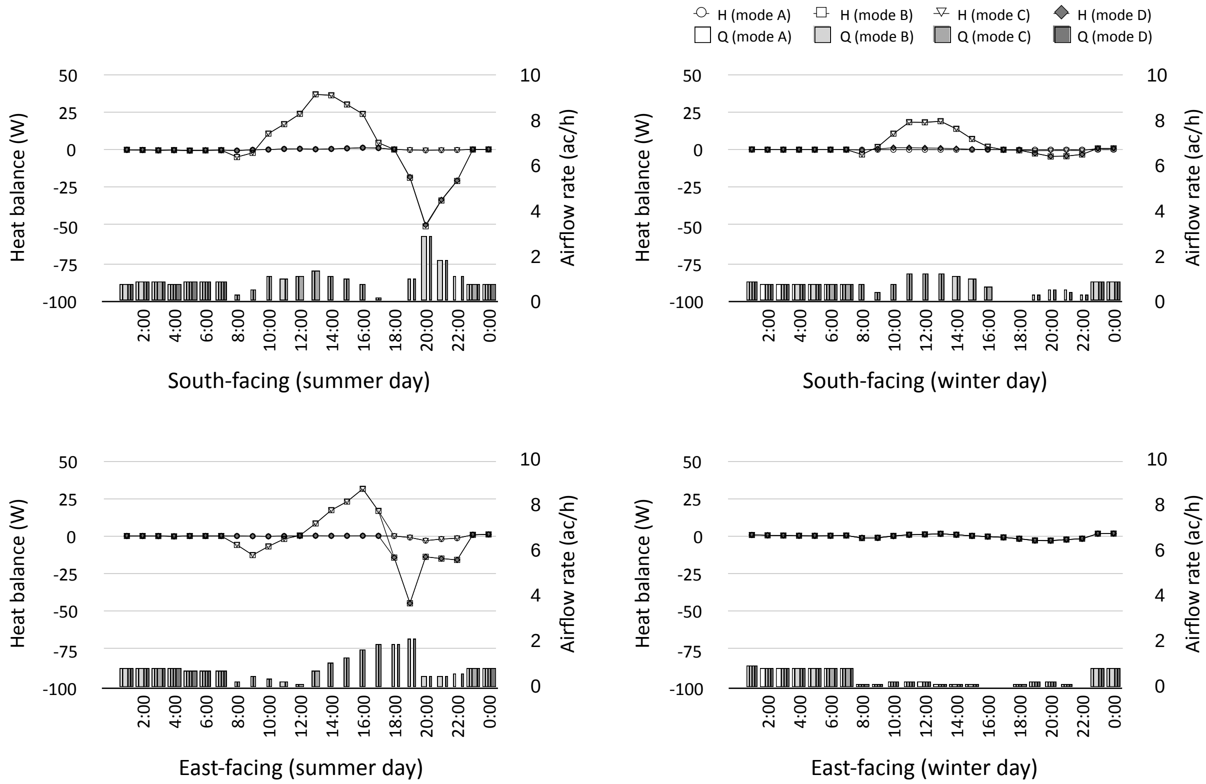

Figure 3: Airflow rate (Q) and heat balance due to external air (H) of South- and East-facing bedroom.

It was found that external airflow rate in all cases was relatively small as the studied bedroom was single-sided ventilated. According to the average wind speed on the summer and winter day of 2.1ms^{-1} and the prevailing wind direction from the North-East, average Q during 8:00-22:00hrs (a/c was off) for South- and East-facing bedrooms were 0.4-1.0 ac/h on the summer day and 0.2-0.7 on the winter day, depending on modes of window use. This was except for '*no ventilation*' cases where average Q due to external air infiltration was found at 0-0.2 ac/h.

The charts in Figure 3 also illustrate that the incoming air has an impact on the bedroom heat balance. This impact depends on airflow rate and the temperature difference between T_{out} and T_a. Greater volume of airflow rate would have a greater impact on the bedroom heat balance, either to increase or decrease it. During the time when T_{out} was greater than T_a such as during 9:00-17:00hrs in South-facing bedroom on the summer day, the incoming air created the heat flow into the bedroom and caused the room T_a to rise (see also T_a of the bedroom with '*day-time ventilation*' on Figure 2). The inverse results were found in the morning and in the evening, for instance, during 8:00-9:00hrs and 18:00-22:00hrs for South-facing bedroom; and during 8:00-11:00hrs and 18:00-22:00hrs for East-facing bedroom. Window use during early morning and, especially, in the evening are therefore preferable for reducing the bedroom T_a and cooling load.

Effect of window uses on bedroom cooling energy

The effect of window uses on the bedroom cooling energy was investigated. Figure 4 illustrates the results of annual cooling energy use of the four-oriented bedrooms with different window uses.

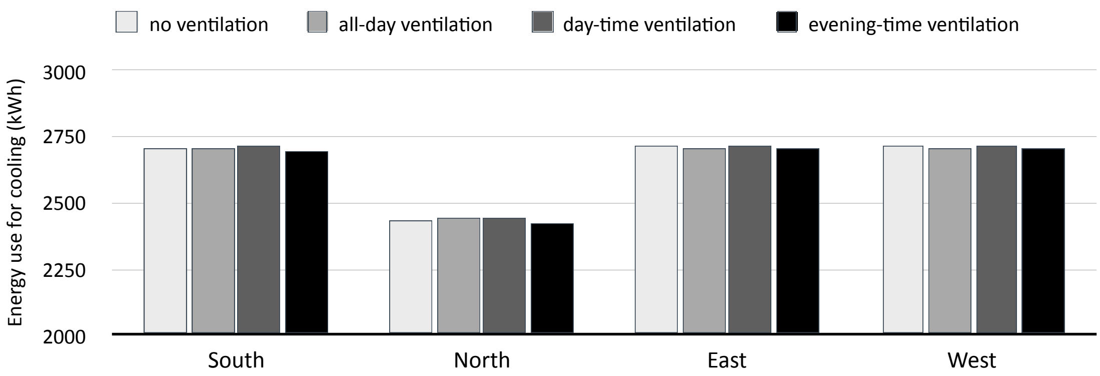

Figure 4: Annual energy use for cooling of the bedrooms with four window uses.

The bedroom cooling energy was found depending on the room's orientation. North-facing bedrooms were found to have the lowest cooling energy for all modes of window use, while other bedrooms had fairly similar results. Different window uses were found to have a slight effect on the bedroom cooling energy. Except for the East-facing, the bedrooms with '*evening-time ventilation'* were found to have the lowest annual cooling energy, followed either by "*all-day ventilation*" for South- and West-facing bedrooms or "*no ventilation*" for North-facing bedroom and the bedrooms with "*day ventilation*" were found to have the highest cooling energy. This was because T_{out} in the evening was relatively lower than the bedrooms' T_a, so the incoming air helped reducing the rooms' T_a and sensible cooling load. On the contrary, the incoming air during daytime, which has relatively higher temperature, increased the bedroom T_a and therefore the room sensible cooling load. The cooling energy difference between the bedrooms with '*evening-time ventilation'* and '*day ventilation'* were found as 13.0-17.6kWh per year, depending on the room's orientation.

For East-facing bedrooms, the bedrooms with '*all-day ventilation'* were found to have the lowest cooling energy, while the bedrooms with "*no ventilation*" had the highest. This was because the bedrooms' T_a rose quickly since the early morning and became greater than T_{out} since then. Therefore, it was not only the incoming air during the evening, but also during the morning (8:00-11:00hrs) could help reducing the East-facing bedroom's T_a and cooling load.

Conclusion

In this study, typical characteristics of high-rise condominiums in Bangkok metropolitan area and the resident behavior were surveyed. It was found that all of the condominiums are the change-over type of mixed-mode buildings. Natural ventilation and a/c are both employed in the same area, but at different time. Most of the residents operated a/c in their bedrooms during the night, regardless of the external climatic conditions. Employing natural ventilation in such case is therefore a challenging issue. Four different modes of window use found from the survey: '*no ventilation*', '*all-day ventilation*', '*day-time ventilation'* and *'evening-time ventilation*' were simulated in this study aiming to discover its effect on the bedroom's cooling energy.

The bedroom's air temperature and cooling energy are found depending greatly on the room's orientation regarding to the sun path. Window use also has an effect on the room's cooling energy. In most cases, the bedroom with *'evening-time ventilation*' has the lowest annual cooling energy, while the room with '*day-time ventilation'* had the highest. This impact of window use depend on external airflow rate and temperature difference between indoor and outdoor air temperature. Greater volume of incoming air would provide a greater effect on increasing or decreasing the bedroom's cooling energy. Window use during the time when outdoor air temperature is relatively lower than indoor air temperature, such as during the early morning and in the evening, is preferable for reducing the room's cooling energy use and could be adapted as a promising post-occupancy strategy to help a mixed-mode building to achieve more energy efficiency. However, the results of airflow rate in this study were very small due to the fact that the studied bedroom was single-sided ventilated. Opening design that allows a greater incoming airflow rate would produce the greater effect of window use on the bedroom's cooling energy use reduction. This issue would be the near future study.

Abstract: The study is focused on the performance evaluation of three types of glazing typically available in the market through the utilization of an office building as a case study located in a hot arid climate zone. The aim of the paper is to enable designers to select the most suitable glazing type through a comparison between different options of available commercial glazing types and study the payback analysis and financial return using market costs. Whereas various climatic regions were taken into consideration in three MENA countries. The baseline used for benchmarking is a clear glazing type compared against the three studied glazing types. Results showes that the SHGC value is the key factor that affects the energy consumption, especially the window solar gain. Another factor that was taken into consideration is the U-value; however, there is a certain threshold for the U-value where its reduction becomes inefficient. A model was developed and tested in several climates to determine whether the threshold would vary from one location to the other. Furthermore, the selection of the most suitable glazing is ultimately a compromise between the economic performance and energy conservation.

Keywords: U-value, curtain wall glazing system, hot (arid/dry) climate, payback analysis, energy Analysis

Introduction

Glazing technologies have advanced in a competitive way that reformed the way choice decisions are made. Decisions are not made through only picking the best properties or the best cost, but a combination of measures and optimized performances are taken to ensure a balanced sustainable choice in terms of economic, environmental and social benefits. Solar heat gain coefficient and the U-value are two of the main properties of a glazing panel that affect its thermal performance. Since glazing is considered one of the most influential performance meters in the building envelope, the slightest change in their values would induce a great change in energy consumption in the building. A variety of glazing materials are used to balance between the amount of light transmitted inside, and amount of heat prevented. Low-E, for example, are spectrally selective coatings applied on the glass panel, which reflects infra-red radiation without any significant loss of visible light transmission. Electro-chromatic material is another application, where it is able to adjust the optical properties of the glass through running voltage. (Granqvist, 1995) (Papaefthimiou, Leftheriotis, & Yianoulis, 2001)

Moreover, decreasing the U-value of the fenestration system is an effective way for energy. One way of doing so is through adding more than one layer of glazing and applying gaseous material in between. Different glazing systems were tested and analyzed in a residential building in California by Sullivan et.al. The single, double and triple-glazed windows were observed against their energy efficiency in different climatic conditions (Sullivan & Selkowitz, 1985). While Rousseau concluded that higher thermal resistance can be observed having a layer of inert gas results in when than single glass panes, which determines that gaseous layers have more thermal impact on the overall U-value than the glass itself (Rousseau, 1988). (Kim, 2011) used a comparative life cycle assessment approach to compare a transparent composite façade system (TCFS) and glass curtain wall system (GCWS). In the assessment he compared both alternatives throughout all stages of their life cycle from an environmental aspect; considering both the energy consumption and the CO_2 emissions. The main recommendations were to carry out further research for different climatic zones, building types and orientations. In addition, it was pointed out that the results could change upon utilizing a dynamic SHGC instead of a single SHGC, therefore its effect should be tested as well.

Methodology

The aim of this paper is to compare the performances of four glazing types (Note: for the academic purpose of this paper, the actual brand names of the four types were renamed to clear, Type T, Type S and Type G). Different weather conditions for three regional locations were chosen: Cairo, Egypt (hot desert climate); Dubai, United Arab Emirates (tropical desert climate), and Algiers, Algeria (temperate zone) as shown in Figure 1.

Figure 1: The three locations selected with different climate conditions

The objective of the paper to serve as a comparative analysis case study with a main purpose to give an insight of how the glazing type chosen will affect the Energy Use Intensity (EUI) in different climatic zones and how the cost of the different glazing would affect the payback period. However, the analysis performed have been based upon simulation tools results, therefore the values given are only accurate if all variable match those of the simulation inputs. For the purpose of glazing selection, the comparative analysis is indeed a useful decision making tool. In the comparison process all the variable and inputs are kept constant for all alternatives, only the glazing specifications are changed. For the analysis to correctly demonstrate the impact of the glazing type key variables were defined based on the client's input data. These variables include, but are not limited to, the building's location, architectural model, and orientation. Nonetheless, the glazing technical specifications like the

U-value and the Solar Heat Gain Coefficient [SHGC] were fundamental inputs for the simulation process. Performing such a comparative analysis required the following work phases:

1. *Modeling* the architectural model with all the details as well as setting the building orientation and location.
2. *Defining* the glazing properties for the clear glass
3. *Performing* an energy simulation analysis and extracting the energy performance data
4. *Altering* the glazing properties to match the other types glass instead of the clear
5. *Obtaining* the energy performance data for the other glazing types and different locations scenarios
6. *Comparing* the energy performances for all scenarios and calculating the energy savings
7. *Calculating* the savings in terms of the price of energy consumption and performing a payback analysis

Glazing Types

The properties of all glazing alternatives are given Table 1 below:

Table 1: Properties of the Alternatives

	Clear	Type-S	Type-T	Type-G
Cross Section				Specification	6mm Clear/16mm A.S/6mm Clear	6mm Tinted Gray+1.14mm PVB+ 4mm clear/20mm A.S/6mm SG 500 low E	6mm Tinted Gray/16mm A.S/6mm Clear	6mm PLANILUX+ COOL-LITE KNT 155/20mmA.S/6mm PLANILUX
U-Value	2.7	1.7 (Air) / 1.5 (Argon)	2.7	1.7
SHGC	0.74	0.37	0.44	0.43
Cost ($/m²)	33.7	69.8	40.5	67.6

Overview of building location and simulation engine

Office building located in New Cairo, Egypt with a north east orientation (angle to north = 36^o).

Figure 2: The location and architectural rendering of the building case study

The choice of the simulation tool was based upon two main criteria; the first is the simulation engine capabilities as well as a flexibility in altering the glazing properties, the second is the modelling complexity. Having an architectural model with elevations mainly of curtain walls and the fact that the glazing is the main element of this analysis, maintaining the model details was extremely crucial. The program used for both modelling and energy simulation is Autodesk Revit®. The energy simulation was carried out using the cloud based energy analysis tool powered by Autodesk Green Studio Energy Analysis, the engine used is DOE 2.2.

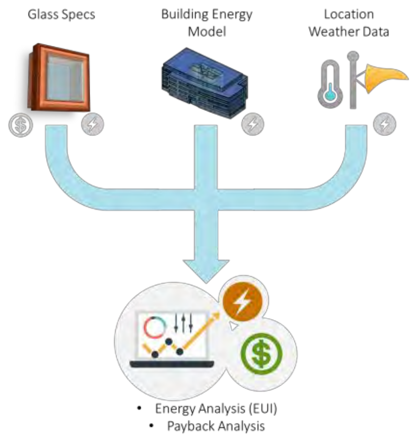

Figure 3: The simulation inputs and outputs

The inputs of the energy simulation were as follows:

- The building model including the main architectural details, and with the actual orientation.
- The glazing specifications as previously mentioned
- The accurate location and the corresponding weather data

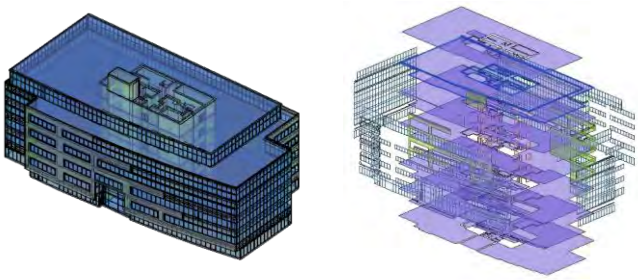

Figure 4: The analytical energy model (left) and the breakdown of the analytical surfaces (right)

For the purpose of creating a comparison between the performances of the four glazing types, four energy simulations were carried out in each of the selected regions. The glazing specifications were altered for the analysis but every other aspect was kept constant. The outputs of interest to this energy analysis are the Energy Use Intensity of the building in kWh/m^2/year and the window solar heat gain in kWh and the space cooling loads in kWh. These outputs were obtained for all the glazing types, hence computing the differences was possible.

Results Overview

The energy simulation results comparison showed that replacing the clear glass with any of the other types that has a lower U-value or a lower SHGC can indeed decrease the EUI, cooling loads, and window solar heat gains. The decrease in the SHGC had a greater impact on the EUI than the decrease in the U-value. However, the reduction percentage of the EUI is associated with the climate area. The improvement in EUI for Dubai scored the highest reductions ranging between 10.6% for Type-S and 8.4% for Type-T, while Algeria scored the lowest improvements of 7.9% only for the Type-S and 6.0% for Type-T. In all climatic zones, Type-S, which has the lowest U-value and lowest SHGC, proved to be the best energy saving while Type-T glass showed the lowest improvements in energy intensity. The differences between all the scenarios is shown in Figure 5 and the percentages in EUI improvement are illustrated in Figure 6.

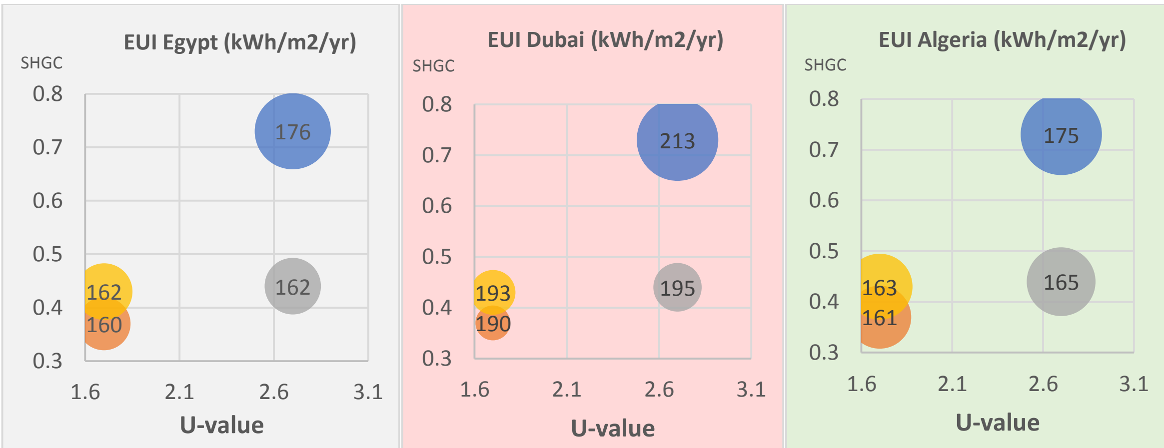

Figure 5: Energy Use Intensity (SHGC as a function of U-value)

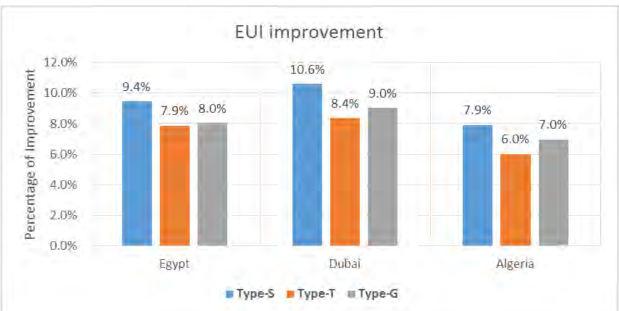

Figure 6: Energy Use Intensity improvement

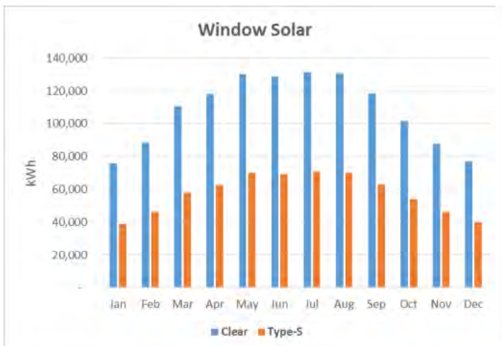

Figure 7: Window Solar Heat Gain per Unit Area

Window Solar Heat Gain, Electricity and HVAC loads savings

Figure 4 above clarifies the impact of using lower SHGC and lower U-value glazing type as the window solar heat gain values have been dramatically reduced. Nonetheless, decreasing the window solar heat gain loads lead to a reduction in the cooling loads and in the HVAC electricity usage. In a hot arid climate like Cairo and Dubai, this reduction in HVAC loads is of great importance and represents a large value of energy savings. The difference in electricity savings is certainly more drastic in summer months reaching up to 12% savings in months like August, September and October, as shown in Figure 8, due to the savings in the HVAC cooling loads. However, for Dubai, the electricity savings has no regular pattern, since the weather in Dubai tends to be warmer all year. As for Algeria, the electricity savings are slightly lower than Dubai and Cairo around the year except for July and August where the savings reached 12%. As for the HVAC savings in all three locations for the three glazing types, Type-S proves to have the highest saving percentage of 22.36%, as shown in Figure 9.

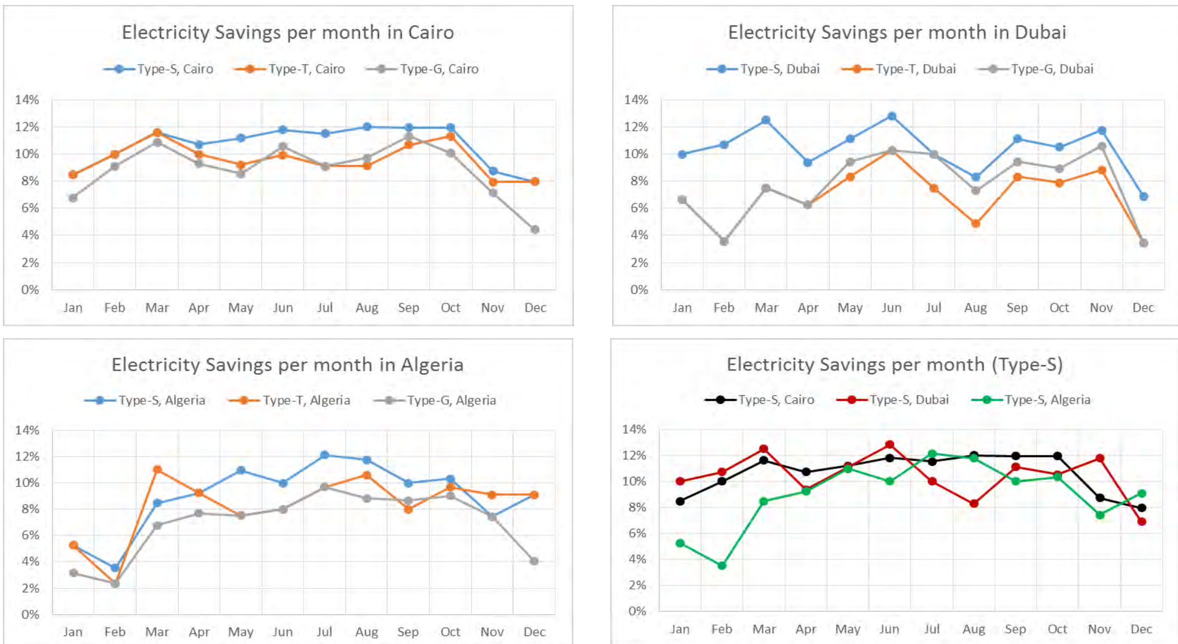

Figure 8: Electricity Savings per Month for Cairo, Dubai and Algeria, and for Type-S per country

On the other hand, the HVAC savings in Dubai was lower than the expected pattern although the impact on the total EUI was higher than other regions, where Dubai's Type-S glazing showed lower improvement than Cairo and Algeria with a value of 17.89% only. This means that the higher temperature would not always result in higher savings. On another note, the savings from the tinted glazing were higher than Type-G in both Cairo and Algeria, however, in Dubai, Type-G would be a better option than the Type-T.

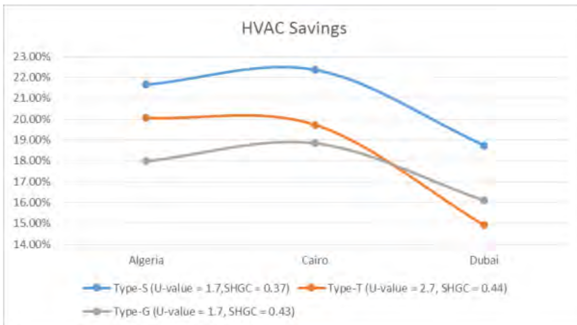

Figure 9: Savings percentages in the HVAC loads

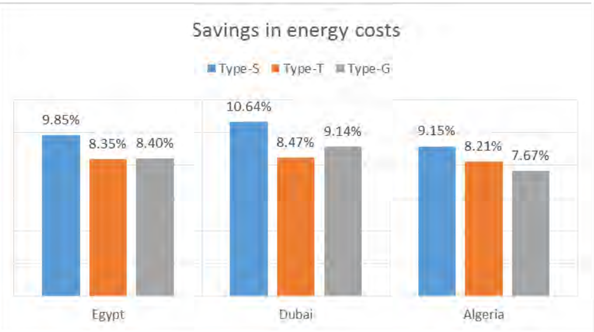

Figure 10: Savings in Energy Costs

Cost analysis

The cost analysis shown in Table 2 was based on the following assumptions list for the electricity and fuel rates for all three regions and an interest rate of 6.1%.

Table 2 List of assumptions for the cost analysis

Parameter	Egypt	Dubai	Algeria
Electricity Rate ($/kWh)	0.05	0.10	0.03
Natural Gas Rate ($/kWh)	0.034	0.05	0.0055
Glass Built Area		3508 m^2	
Interest rate		6.1%	

Cost savings & Payback analysis

The energy savings, in terms of cost (Figure 10), achieved with Type-S is the highest among the three locations, saving in the yearly energy running costs for the given building. Noting that the price of energy has been assumed as noted in Table 2 (Tariffs, 2016) (Slab Tarrif, 2016). The investment results for Cairo, Egypt are shown in Figure 11, the payback period is about 7.06 years for Type-S, 14.20 years for Type-G and 3.10 years for Type-T glass. It can be concluded that both the Type-S and Type-T glass are cost effective alternatives as their life-time is at least 10 years, this means the differences in their costs will in fact be paid back in terms of energy costs savings.

The Type-G payback period exceeds its estimated 10 years life-time by 4.20 years, although it has better energy savings than Type-T glazing, which means this alternative is not applicable Cairo. However, in Dubai all three alternatives' payback period are within the 10-years range as shown in Figure 12. In fact, all three alternatives have lower payback periods than in Cairo with 1.26 years for Type-T glass option, 2.71 years for the Type-S, and 5.40 years for Type-G. As for Algeria, only Type-T glass is within the 10-years range with 5.66 years while Type-S and Type-G options are economically inapplicable.

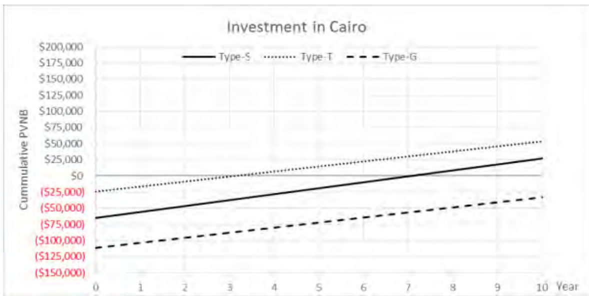

Figure 11: Payback Analysis for Type-S, Type-G and Type-T Glass in Cairo

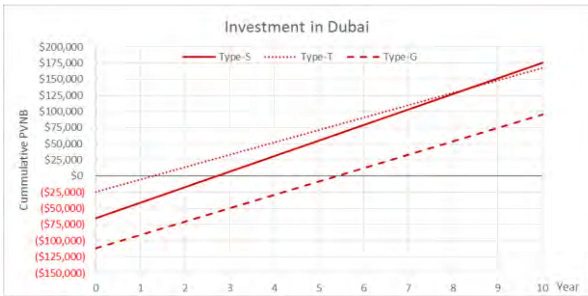

Figure 12 Payback Analysis for Type-S, Type-G and Type-T Glass in Dubai

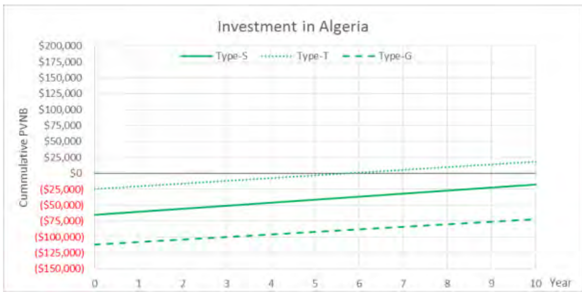

Figure 13 Payback Analysis for Type-S, Type-G and Type-T glass in Algeria

Conclusion

There are two aspects in which the selection criteria can be based upon: Economical effectiveness and Energy-efficiency. From the energy efficiency point of view Type-S displayed the highest records of energy savings in all regions. Although it is economically effective in countries with higher fuel costs, as the payback period for both is less than their life time in Dubai and Cairo, Type-T glass is the most economically effective choice for it recorded the lowest payback period in all three regions and it is highly recommended in Algeria. Both the SHGC and the U-value affect the energy efficiency of the building; however, the SHGC was a more effective factor in saving energy compared to the U-value.

Abstract: Window is an important part of the building envelope. Although the presence of large window surfaces could be preferable for daylighting and sightseeing. However, more attention has to be paid to limit the transmittance of solar radiation which causes the increase of cooling load during the cooling season. Energy consumption caused by window accounts for a large proportion in the whole building cooling energy consumption. However, the choice of glazing type and the design of windows on a façade may depend on comfort consideration as well as their energy performances. In other words, an energy-saving window glass have to be able to simultaneously take into account the indoor visual and thermal comfort, as well as the energy consumption from lighting system and air conditioning system. Since this field of knowledge lacks experimental quantitative analysis, the purposes of this study are to explore the quantify the effectiveness of the related parameters for the selection of a suitable window glass in perspectives of indoor thermal comfort and energy use. A full-scale experiment was conducted in six experimental chambers against six different types of glass for studying their influences of indoor thermal comfort and the cooling energy use

Keywords: Window glass; Thermal comfort; Energy use

Introduction

Window enables visual access to outdoor scenery and is one of crucial building envelope component. It is capable of providing natural lighting and, from the results of many existing studies, could increase occupants' working efficiency. However, the fenestration is the most vulnerable part regarding its thermal resistance as opposed to opaque walls or roofs. Air-conditioning cooling loads that are gained from solar radiation via windows in summer comprise a considerable proportion of total cooling loads in hot-and-humid regions, such as Taiwan. The excessive heat gain through the windows would not only increase the cooling energy but also would deteriorate the indoor thermal comfort. The fundamental performance parameters of glass related to lighting, thermal environment and cooling energy are: (1) coefficient of conductivity (U-value), which evaluates conductive heat gains by indoor-outdoor surface temperature difference; (2) shading coefficient (SC) or solar heat gain coefficient(SHGC), which for instance of SC, is the ratio of solar radiation heat gain in comparison of a 3mm clear plane glass. The SC value is characterized by 0~1, the larger the number the more solar radiation is gained indoors, and vice versa; and (3) visibility transmittance(VT), which denotes the proportion of transmittance of the visible light. Larger VT suggests there are more visible lights coming inside resulting better natural daylighting. By means of adequate architectural daylighting design, it could reduce the artificial lighting energy and decrease its heat gain. The range of VT would widely vary with the types of glass, number of glass layers and the glass coatings.

This study firstly reviewed the research progress regarding the influence of glass's performance on indoor thermal comfort and cooling energy use. Furthermore, a set of long-term experiments were conducted with six full-scale experimental chambers each installed with different types of glass, including double low energy glass, double reflective glass, double tinted glass, single electrochromic glass, single tinted glass and single clear glass. The objective of this research is to investigate the influences of thermal and optical factors of glass on the performances of indoor thermal environment and cooling energy of buildings.

Methodology

Energy efficient glass and window heat conduction

Currently there are no specific definition of energy efficient glass and physical evaluation index of it in Taiwan. Energy efficient glass is a relative term by comparing its performance to general clear plane glass. The heat flow of a glass pane comprises temperature driven heat conductance and solar radiation heat gain. The fundamental handbook of American Society of Heating, Refrigerating and Air-conditioning Engineers (ASHRAE) gave the equational relation of window heat gain as Eq.1. The first term of the equation denotes surface-temperature driven heat conduction, which is calculated by the U-value (U) of glass multiplied by the temperature difference of exterior surface (Tout) and interior surface (Tout); and the second term is for calculating solar radiation heat gains, which is given by multiplying glass's SHGC with solar insolation. It indicates U-value and SHGC are major factors that influence the heat gain from windows. Therefore, National Fenestration Rating Council (NFRC) of the United States adopts U-value and SHGC as crucial factors of glass for thermal performance evaluation purpose.

$$q = U \times (T_{out} - T_{in}) + SHGC \times G \tag{1}$$

Thermal comfort and the fenestration

According to ISO7730 (ISO, 2005), PMV-PPD model has been widely adopted for evaluating indoor thermal comfort. The primary factors that are related to the thermal comfort are ambient temperature, mean radiant temperature, relative humidity and air velocity based on the PMV-PPD model. Lyons et al. (Lyons, Arasteh et al. 2000) emphasized that to quantify the effect of the window glass on occupants' thermal comfort, two additional factors, direct and diffuse solar radiation, should be considered except for the longwave radiation from the surrounding surfaces. Arens et al. (Arens, Gonzalez et al., 1986) and Sullivan (Sullivan, 1986) linearly estimated the PPD in the presence of direct solar radiation, as depicted in Figure 1. The solar-adjusted PPD was calculated from the net PMV obtained from the summation of the thermal comfort tool calculated PMV under no solar presence circumstance and that of the solar-adjusted PMV. Once the non-solar-existed and solar-existed PPD are known, the value of PPD under the sole influence of the sun, which is ΔPPDsolar, can be obtained by simple arithmetic deduction. Namely, the net PMV is the sum of the non-solar-existed PMV and the solar-adjusted PMV. The ΔPPDsolar can be derived from deducting the total PPD (PPDtotal) by the surface-influenced PPD (PPDsurface), and is given by:

$$PPD_{total} = PPD_{surface} + \Delta PPD_{solar} \tag{2}$$

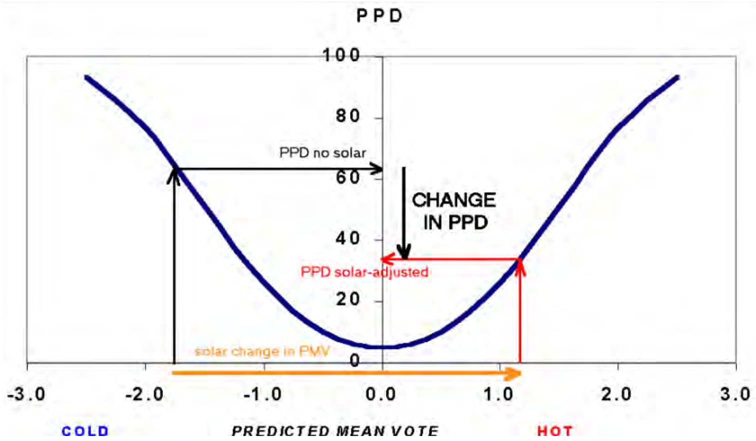

Figure 1 Concept of Solar Adjusted PPD-PMV

The Full Scale Experiment

To understand the thermal comfort variation due to the aforementioned theory and the cooling energy efficiency of various fenestration glass, six full-scale experimental chambers each installed with a variable-speed split-type air conditioner were constructed located at southern Taiwan, as show in Figure 2. Each experimental chamber was remodeled from a standard 20ft shipping container (6.09 m in length, 2.44 m in width and 2.59 m in height) with the interior floor area being 14.4m2. The six experimental chambers were identical in their geometries, thermal resistances of exterior opaque walls, interior configurations, air-tightness of the fenestration. The experimental fenestration surfaces were all at the west side façade of the chamber and each were made of two panes of 1.0 m by 2.0 m glass with a fenestration area of 4 m2. The types of glass for experiment and their thermal properties are listed in Table 1, the U-values range from 2.5 to 5.6 W/m2K and the values of SHGC range from 0.28 to 0.85. The 8 mm single clear glass is regarded as a reference as this is the most commonly seen glass used in Taiwan.

The monitored parameters, including the electricity usage of the air conditioner, indoor air temperature, relative humidity, globe temperature as well as air velocity were recorded by sensors or instruments listed in Table 2. The air-conditioners' electricity consumptions were recorded by digital electricity meters. The thermal comfort measurement was conducted by two sets of thermal environmental monitoring system, one was placed at 1.5 m away from the fenestration and the other was placed 4.5 m away from the fenestration, each for measuring the solar affected and the non-solar affected thermal conditions. The measurement was recorded with a frequency of 2 minutes and sampling at 2 Hz for each sensor

Figure 2: Full-Scale Experimental Platforms for Building Energy Research.

Table 1: Thermal Properties of the Experimented Glass

Exp. no.	Layers of glass	U-value ($W/m^2.K$)	SHGC
1	8mm single clear glass	5.6	0.85
2	8mm single tinted glass	5.6	0.52
3	8mm single electrochromic glass	5.2	0.38

Air velocity	Anemometer	Delta HD2103.2	±0.01m/s
Luminance	Lux meter	HOBO HE140	±3%

Results and discussion

The experiment was performed during 24th May to 6th June, 2016. The maximum daily outdoor air temperatures during the experimental period were all above 33.0C with the average temperatures being 30.0°C except for days of 24th May and 2nd June. The daily averaged relative humidity was 70%-90%. The PMV calculated by the measured hourly dry-bulb temperature, globe temperature and air velocity was presented in Figure 3. We observed that the case of 8mm single clear glass exhibited the highest discomfort against all cases; and the case of electrochromic glass and the double tinted glass exhibited a relatively low potential of indoor overheating.

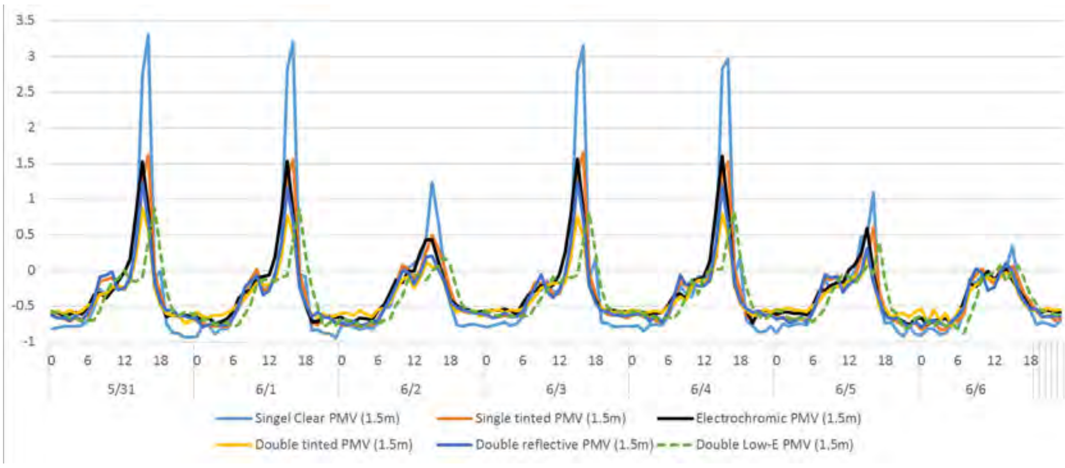

Figure 3: Comparisons of The Calculated PMV 1.5m Away from the Fenestration

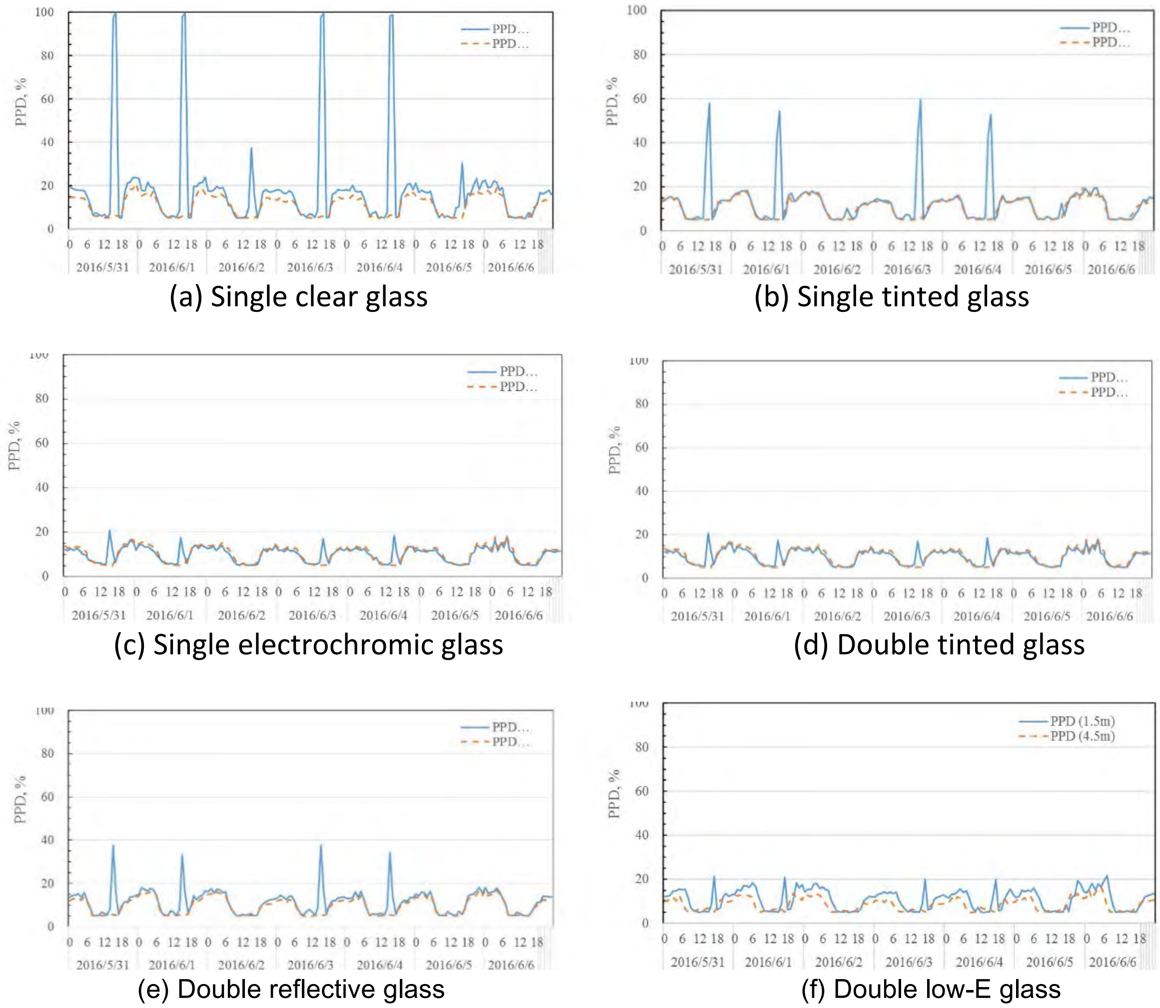
The PPD of single clear glass ranged from circa 5%-20%. However, the PPD near to the fenestration was 95% in the everyday afternoon when the direct solar radiation stroke in during the experiment, as shown in Figure 4(a), suggesting a higher thermal discomfort potential at noon. The PPD range of single tinted glass was also mostly around 5%-20% with the highest value of slightly over 50% at noon, as illustrated in Figure 4(b). The daily temporal PPD variations of electrochromic glass, double tinted glass, double reflective glass, double low-E glass were diagramed in Figure 4(c) to Figure 4(f), respectively. In general, the indoor thermal comfort of windows with double glass glazing performed better than single glass.



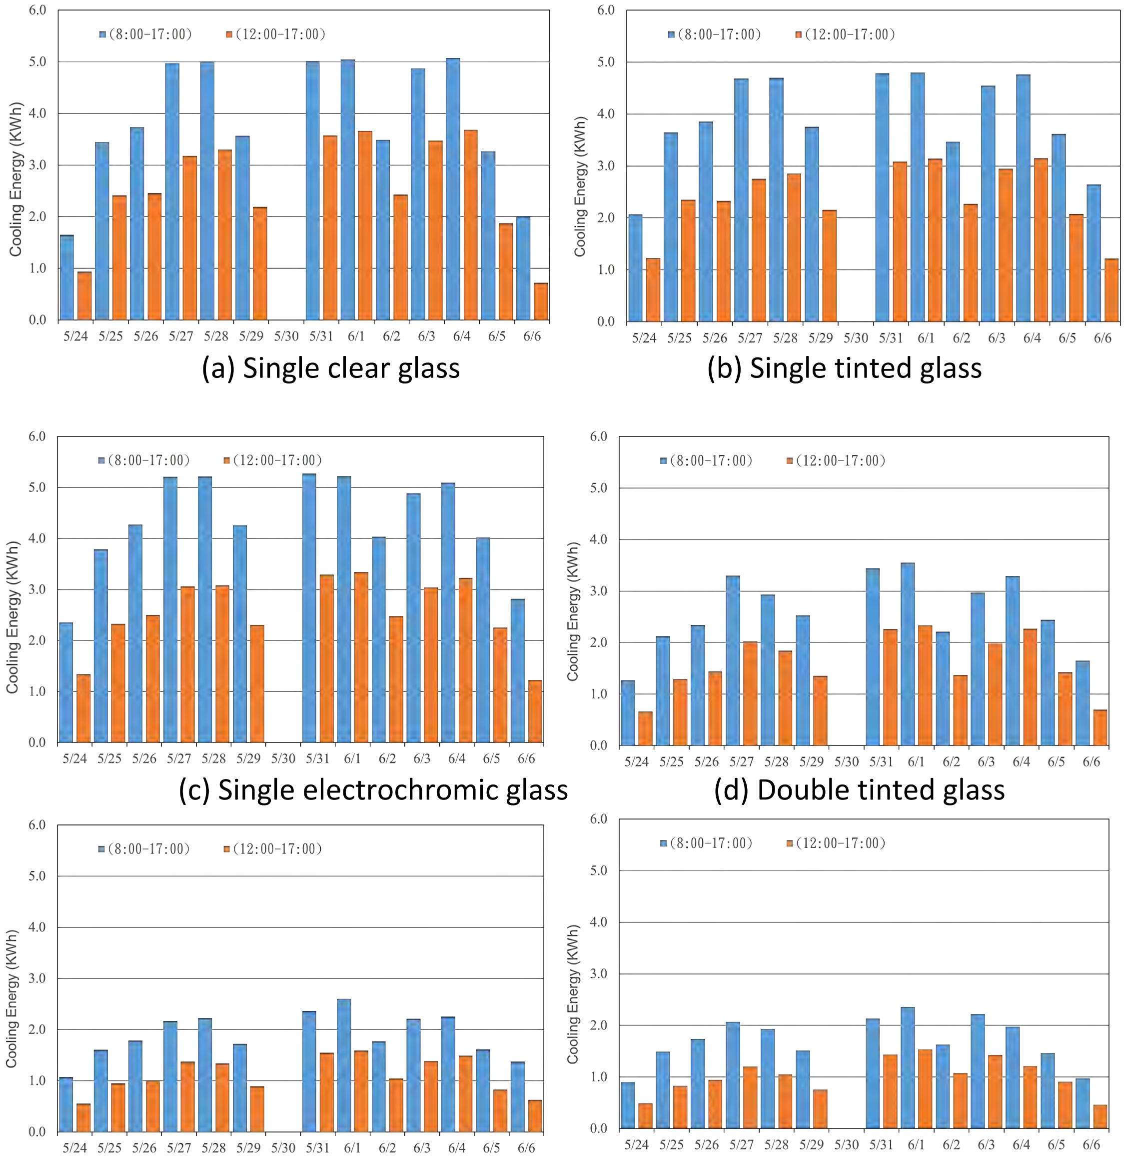
(a) Single clear glass (b) Single tinted glass

(c) Single electrochromic glass (d) Double tinted glass

(e) Double reflective glass (f) Double low-E glass

Figure 4: Daily Indoor PPD Variations of Various Types of Glass.

During the period of experiment, the air-conditioning was kept operating, hence, the daily cooling energy of each case can be obtained by accumulating the hourly electricity meters of air-conditioners in a daily manner. Figure 5 depicted the daily cooling electricity consumptions of all six cases. Since the windows of the experimental chambers are all facing west, the cooling energy uses in the afternoon (12:00-17:00) were also illustrated for comparison. In general double layered glass had lower cooling energy than single layered glass. We discovered that the cases of low-E glass and double reflective glass consumed less cooling energy than the others, followed by the case of double tinted glass. Interestingly, the single tinted glass outperformed the electrochromic glass in term of energy efficiency.



(a) Single clear glass (b) Single tinted glass

(c) Single electrochromic glass (d) Double tinted glass

(e) Double reflective glass (f) Double low-E glass

Figure 5: Daily Cooling Electricity Consumptions of the Six Cases.

Conclusion

The proper selection of fenestration glass has a significant impact on the indoor occupants' thermal comfort as well as cooling energy use. The thermal properties of thermal resistance and shading coefficient of a glass should be both synthetically considered during building fenestration design. Moreover, the selection of glass should also consider local climate to meet energy conservation needs and also fulfill the demand of occupants' thermal comfort. In this study, we investigated the thermal comfort and the energy performances of six common seen fenestration glass by conducting experiments in full-scale experimental chambers in a climate context of hot-and-humid. The results revealed that double layered glass with a lower SHGC would have better performances in indoor thermal comfort as well as cooling energy consumption.
